1. Kaleidoscope: Kaleidoscope Introduction and the Lexer ¶

1.1. The Kaleidoscope Language ¶

This tutorial is illustrated with a toy language called "Kaleidoscope" (derived from "meaning beautiful, form, and view"). Kaleidoscope is a procedural language that allows you to define functions, use conditionals, math, etc. Over the course of the tutorial, we'll extend Kaleidoscope to support the if/then/else construct, a for loop, user defined operators, JIT compilation with a simple command line interface, debug info, etc.

We want to keep things simple, so the only datatype in Kaleidoscope is a 64-bit floating point type (aka 'double' in C parlance). As such, all values are implicitly double precision and the language doesn't require type declarations. This gives the language a very nice and simple syntax. For example, the following simple example computes Fibonacci numbers:

```
# Compute the x'th fibonacci number.
def fib(x)
  if x < 3 then
    1
  else
    fib(x-1)+fib(x-2)

# This expression will compute the 40th number.
fib(40)
```

We also allow Kaleidoscope to call into standard library functions - the LLVM JIT makes this really easy. This means that you can use the 'extern' keyword to define a function before you use it (this is also useful for mutually recursive functions). For example:

```
extern sin(arg);
extern cos(arg);
extern atan2(arg1 arg2);

atan2(sin(.4), cos(42))
```

A more interesting example is included in Chapter 6 where we write a little Kaleidoscope application that displays a Mandelbrot Set at various levels of magnification.

Let's dive into the implementation of this language!

1.2. The Lexer ¶

When it comes to implementing a language, the first thing needed is the ability to process a text file and recognize what it says. The traditional way to do this is to use a "lexer" (aka 'scanner') to

break the input up into “tokens”. Each token returned by the lexer includes a token code and potentially some metadata (e.g. the numeric value of a number). First, we define the possibilities:

```
// The lexer returns tokens [0-255] if it is an unknown character, otherwise one
// of these for known things.
enum Token {
  tok_eof = -1,

  // commands
  tok_def = -2,
  tok_extern = -3,

  // primary
  tok_identifier = -4,
  tok_number = -5,
};

static std::string IdentifierStr; // Filled in if tok_identifier
static double NumVal;             // Filled in if tok_number
```

Each token returned by our lexer will either be one of the Token enum values or it will be an ‘unknown’ character like ‘+’, which is returned as its ASCII value. If the current token is an identifier, the `IdentifierStr` global variable holds the name of the identifier. If the current token is a numeric literal (like 1.0), `NumVal` holds its value. We use global variables for simplicity, but this is not the best choice for a real language implementation :).

The actual implementation of the lexer is a single function named `gettok`. The `gettok` function is called to return the next token from standard input. Its definition starts as:

```
/// gettok - Return the next token from standard input.
static int gettok() {
  static int LastChar = ' ';

  // Skip any whitespace.
  while (isspace(LastChar))
    LastChar = getchar();
```

`gettok` works by calling the C `getchar()` function to read characters one at a time from standard input. It eats them as it recognizes them and stores the last character read, but not processed, in LastChar. The first thing that it has to do is ignore whitespace between tokens. This is accomplished with the loop above.

The next thing `gettok` needs to do is recognize identifiers and specific keywords like “def”. Kaleidoscope does this with this simple loop:

```
if (isalpha(LastChar)) { // identifier: [a-zA-Z][a-zA-Z0-9]*
  IdentifierStr = LastChar;
  while (isalnum((LastChar = getchar())))
    IdentifierStr += LastChar;

  if (IdentifierStr == "def")
```

```
    return tok_def;
  if (IdentifierStr == "extern")
    return tok_extern;
  return tok_identifier;
}
```

Note that this code sets the '`IdentifierStr`' global whenever it lexes an identifier. Also, since language keywords are matched by the same loop, we handle them here inline. Numeric values are similar:

```
if (isdigit(LastChar) || LastChar == '.') {   // Number: [0-9.]+
  std::string NumStr;
  do {
    NumStr += LastChar;
    LastChar = getchar();
  } while (isdigit(LastChar) || LastChar == '.');

  NumVal = strtod(NumStr.c_str(), 0);
  return tok_number;
}
```

This is all pretty straightforward code for processing input. When reading a numeric value from input, we use the C `strtod` function to convert it to a numeric value that we store in `NumVal`. Note that this isn't doing sufficient error checking: it will incorrectly read "1.23.45.67" and handle it as if you typed in "1.23". Feel free to extend it! Next we handle comments:

```
if (LastChar == '#') {
  // Comment until end of line.
  do
    LastChar = getchar();
  while (LastChar != EOF && LastChar != '\n' && LastChar != '\r');

  if (LastChar != EOF)
    return gettok();
}
```

We handle comments by skipping to the end of the line and then return the next token. Finally, if the input doesn't match one of the above cases, it is either an operator character like '+' or the end of the file. These are handled with this code:

```
  // Check for end of file.  Don't eat the EOF.
  if (LastChar == EOF)
    return tok_eof;

  // Otherwise, just return the character as its ascii value.
  int ThisChar = LastChar;
  LastChar = getchar();
  return ThisChar;
}
```

With this, we have the complete lexer for the basic Kaleidoscope language (the full code listing for the Lexer is available in the next chapter of the tutorial). Next we'll build a simple parser that uses

this to build an Abstract Syntax Tree. When we have that, we'll include a driver so that you can use the lexer and parser together.

Next: Implementing a Parser and AST

2. Kaleidoscope: Implementing a Parser and AST ¶

2.1. Chapter 2 Introduction ¶

Welcome to Chapter 2 of the "Implementing a language with LLVM" tutorial. This chapter shows you how to use the lexer, built in Chapter 1, to build a full parser for our Kaleidoscope language. Once we have a parser, we'll define and build an Abstract Syntax Tree (AST).

The parser we will build uses a combination of Recursive Descent Parsing and Operator-Precedence Parsing to parse the Kaleidoscope language (the latter for binary expressions and the former for everything else). Before we get to parsing though, let's talk about the output of the parser: the Abstract Syntax Tree.

2.2. The Abstract Syntax Tree (AST) ¶

The AST for a program captures its behavior in such a way that it is easy for later stages of the compiler (e.g. code generation) to interpret. We basically want one object for each construct in the language, and the AST should closely model the language. In Kaleidoscope, we have expressions, a prototype, and a function object. We'll start with expressions first:

```
/// ExprAST - Base class for all expression nodes.
class ExprAST {
public:
  virtual ~ExprAST() = default;
};

/// NumberExprAST - Expression class for numeric literals like "1.0".
class NumberExprAST : public ExprAST {
  double Val;
```

```
public:
  NumberExprAST(double Val) : Val(Val) {}
};
```

The code above shows the definition of the base ExprAST class and one subclass which we use for numeric literals. The important thing to note about this code is that the NumberExprAST class captures the numeric value of the literal as an instance variable. This allows later phases of the compiler to know what the stored numeric value is.

Right now we only create the AST, so there are no useful accessor methods on them. It would be very easy to add a virtual method to pretty print the code, for example. Here are the other expression AST node definitions that we'll use in the basic form of the Kaleidoscope language:

```
/// VariableExprAST - Expression class for referencing a variable, like "a".
class VariableExprAST : public ExprAST {
  std::string Name;

public:
  VariableExprAST(const std::string &Name) : Name(Name) {}
};

/// BinaryExprAST - Expression class for a binary operator.
class BinaryExprAST : public ExprAST {
  char Op;
  std::unique_ptr<ExprAST> LHS, RHS;

public:
  BinaryExprAST(char Op, std::unique_ptr<ExprAST> LHS,
                std::unique_ptr<ExprAST> RHS)
    : Op(Op), LHS(std::move(LHS)), RHS(std::move(RHS)) {}
};

/// CallExprAST - Expression class for function calls.
class CallExprAST : public ExprAST {
  std::string Callee;
  std::vector<std::unique_ptr<ExprAST>> Args;

public:
  CallExprAST(const std::string &Callee,
              std::vector<std::unique_ptr<ExprAST>> Args)
    : Callee(Callee), Args(std::move(Args)) {}
};
```

This is all (intentionally) rather straight-forward: variables capture the variable name, binary operators capture their opcode (e.g. '+'), and calls capture a function name as well as a list of any argument expressions. One thing that is nice about our AST is that it captures the language features without talking about the syntax of the language. Note that there is no discussion about precedence of binary operators, lexical structure, etc.

For our basic language, these are all of the expression nodes we'll define. Because it doesn't have conditional control flow, it isn't Turing-complete; we'll fix that in a later installment. The two

things we need next are a way to talk about the interface to a function, and a way to talk about functions themselves:

```
/// PrototypeAST - This class represents the "prototype" for a function,
/// which captures its name, and its argument names (thus implicitly the number
/// of arguments the function takes).
class PrototypeAST {
  std::string Name;
  std::vector<std::string> Args;

public:
  PrototypeAST(const std::string &Name, std::vector<std::string> Args)
    : Name(Name), Args(std::move(Args)) {}

  const std::string &getName() const { return Name; }
};

/// FunctionAST - This class represents a function definition itself.
class FunctionAST {
  std::unique_ptr<PrototypeAST> Proto;
  std::unique_ptr<ExprAST> Body;

public:
  FunctionAST(std::unique_ptr<PrototypeAST> Proto,
              std::unique_ptr<ExprAST> Body)
    : Proto(std::move(Proto)), Body(std::move(Body)) {}
};
```

In Kaleidoscope, functions are typed with just a count of their arguments. Since all values are double precision floating point, the type of each argument doesn't need to be stored anywhere. In a more aggressive and realistic language, the "ExprAST" class would probably have a type field.

With this scaffolding, we can now talk about parsing expressions and function bodies in Kaleidoscope.

2.3. Parser Basics ¶

Now that we have an AST to build, we need to define the parser code to build it. The idea here is that we want to parse something like "x+y" (which is returned as three tokens by the lexer) into an AST that could be generated with calls like this:

```
auto LHS = std::make_unique<VariableExprAST>("x");
auto RHS = std::make_unique<VariableExprAST>("y");
auto Result = std::make_unique<BinaryExprAST>('+', std::move(LHS),
                                              std::move(RHS));
```

In order to do this, we'll start by defining some basic helper routines:

```
/// CurTok/getNextToken - Provide a simple token buffer.  CurTok is the current
/// token the parser is looking at.  getNextToken reads another token from the
/// lexer and updates CurTok with its results.
static int CurTok;
static int getNextToken() {
```

```
  return CurTok = gettok();
}
```

This implements a simple token buffer around the lexer. This allows us to look one token ahead at what the lexer is returning. Every function in our parser will assume that CurTok is the current token that needs to be parsed.

```
/// LogError* - These are little helper functions for error handling.
std::unique_ptr<ExprAST> LogError(const char *Str) {
  fprintf(stderr, "Error: %s\n", Str);
  return nullptr;
}
std::unique_ptr<PrototypeAST> LogErrorP(const char *Str) {
  LogError(Str);
  return nullptr;
}
```

The LogError routines are simple helper routines that our parser will use to handle errors. The error recovery in our parser will not be the best and is not particular user-friendly, but it will be enough for our tutorial. These routines make it easier to handle errors in routines that have various return types: they always return null.

With these basic helper functions, we can implement the first piece of our grammar: numeric literals.

2.4. Basic Expression Parsing ¶

We start with numeric literals, because they are the simplest to process. For each production in our grammar, we'll define a function which parses that production. For numeric literals, we have:

```
/// numberexpr ::= number
static std::unique_ptr<ExprAST> ParseNumberExpr() {
  auto Result = std::make_unique<NumberExprAST>(NumVal);
  getNextToken(); // consume the number
  return std::move(Result);
}
```

This routine is very simple: it expects to be called when the current token is a tok_number token. It takes the current number value, creates a NumberExprAST node, advances the lexer to the next token, and finally returns.

There are some interesting aspects to this. The most important one is that this routine eats all of the tokens that correspond to the production and returns the lexer buffer with the next token (which is not part of the grammar production) ready to go. This is a fairly standard way to go for recursive descent parsers. For a better example, the parenthesis operator is defined like this:

```
/// parenexpr ::= '(' expression ')'
static std::unique_ptr<ExprAST> ParseParenExpr() {
  getNextToken(); // eat (.
  auto V = ParseExpression();
  if (!V)
```

```
    return nullptr;

  if (CurTok != ')')
    return LogError("expected ')'");
  getNextToken(); // eat ).
  return V;
}
```

This function illustrates a number of interesting things about the parser:

1) It shows how we use the LogError routines. When called, this function expects that the current token is a '(' token, but after parsing the subexpression, it is possible that there is no ')' waiting. For example, if the user types in "(4 x" instead of "(4)", the parser should emit an error. Because errors can occur, the parser needs a way to indicate that they happened: in our parser, we return null on an error.

2) Another interesting aspect of this function is that it uses recursion by calling `ParseExpression` (we will soon see that `ParseExpression` can call `ParseParenExpr`). This is powerful because it allows us to handle recursive grammars, and keeps each production very simple. Note that parentheses do not cause construction of AST nodes themselves. While we could do it this way, the most important role of parentheses are to guide the parser and provide grouping. Once the parser constructs the AST, parentheses are not needed.

The next simple production is for handling variable references and function calls:

```
/// identifierexpr
///   ::= identifier
///   ::= identifier '(' expression* ')'
static std::unique_ptr<ExprAST> ParseIdentifierExpr() {
  std::string IdName = IdentifierStr;

  getNextToken();  // eat identifier.

  if (CurTok != '(') // Simple variable ref.
    return std::make_unique<VariableExprAST>(IdName);

  // Call.
  getNextToken();  // eat (
  std::vector<std::unique_ptr<ExprAST>> Args;
  if (CurTok != ')') {
    while (true) {
      if (auto Arg = ParseExpression())
        Args.push_back(std::move(Arg));
      else
        return nullptr;

      if (CurTok == ')')
        break;

      if (CurTok != ',')
        return LogError("Expected ')' or ',' in argument list");
      getNextToken();
    }
  }
```

```
  // Eat the ')'.
  getNextToken();

  return std::make_unique<CallExprAST>(IdName, std::move(Args));
}
```

This routine follows the same style as the other routines. (It expects to be called if the current token is a `tok_identifier` token). It also has recursion and error handling. One interesting aspect of this is that it uses *look-ahead* to determine if the current identifier is a stand alone variable reference or if it is a function call expression. It handles this by checking to see if the token after the identifier is a '(' token, constructing either a `VariableExprAST` or `CallExprAST` node as appropriate.

Now that we have all of our simple expression-parsing logic in place, we can define a helper function to wrap it together into one entry point. We call this class of expressions "primary" expressions, for reasons that will become more clear later in the tutorial. In order to parse an arbitrary primary expression, we need to determine what sort of expression it is:

```
/// primary
///   ::= identifierexpr
///   ::= numberexpr
///   ::= parenexpr
static std::unique_ptr<ExprAST> ParsePrimary() {
  switch (CurTok) {
  default:
    return LogError("unknown token when expecting an expression");
  case tok_identifier:
    return ParseIdentifierExpr();
  case tok_number:
    return ParseNumberExpr();
  case '(':
    return ParseParenExpr();
  }
}
```

Now that you see the definition of this function, it is more obvious why we can assume the state of CurTok in the various functions. This uses look-ahead to determine which sort of expression is being inspected, and then parses it with a function call.

Now that basic expressions are handled, we need to handle binary expressions. They are a bit more complex.

2.5. Binary Expression Parsing ¶

Binary expressions are significantly harder to parse because they are often ambiguous. For example, when given the string "x+y*z", the parser can choose to parse it as either "(x+y)*z" or "x+(y*z)". With common definitions from mathematics, we expect the later parse, because "*" (multiplication) has higher *precedence* than "+" (addition).

There are many ways to handle this, but an elegant and efficient way is to use Operator-Precedence Parsing. This parsing technique uses the precedence of binary operators to guide recursion. To start with, we need a table of precedences:

```
/// BinopPrecedence - This holds the precedence for each binary operator that is
/// defined.
static std::map<char, int> BinopPrecedence;

/// GetTokPrecedence - Get the precedence of the pending binary operator token.
static int GetTokPrecedence() {
  if (!isascii(CurTok))
    return -1;

  // Make sure it's a declared binop.
  int TokPrec = BinopPrecedence[CurTok];
  if (TokPrec <= 0) return -1;
  return TokPrec;
}

int main() {
  // Install standard binary operators.
  // 1 is lowest precedence.
  BinopPrecedence['<'] = 10;
  BinopPrecedence['+'] = 20;
  BinopPrecedence['-'] = 20;
  BinopPrecedence['*'] = 40;  // highest.
  ...
}
```

For the basic form of Kaleidoscope, we will only support 4 binary operators (this can obviously be extended by you, our brave and intrepid reader). The `GetTokPrecedence` function returns the precedence for the current token, or -1 if the token is not a binary operator. Having a map makes it easy to add new operators and makes it clear that the algorithm doesn't depend on the specific operators involved, but it would be easy enough to eliminate the map and do the comparisons in the `GetTokPrecedence` function. (Or just use a fixed-size array).

With the helper above defined, we can now start parsing binary expressions. The basic idea of operator precedence parsing is to break down an expression with potentially ambiguous binary operators into pieces. Consider, for example, the expression "a+b+(c+d)*e*f+g". Operator precedence parsing considers this as a stream of primary expressions separated by binary operators. As such, it will first parse the leading primary expression "a", then it will see the pairs [+, b] [+, (c+d)] [*, e] [*, f] and [+, g]. Note that because parentheses are primary expressions, the binary expression parser doesn't need to worry about nested subexpressions like (c+d) at all.

To start, an expression is a primary expression potentially followed by a sequence of [binop,primaryexpr] pairs:

```
/// expression
///   ::= primary binoprhs
///
static std::unique_ptr<ExprAST> ParseExpression() {
```

```
  auto LHS = ParsePrimary();
  if (!LHS)
    return nullptr;

  return ParseBinOpRHS(0, std::move(LHS));
}
```

ParseBinOpRHS is the function that parses the sequence of pairs for us. It takes a precedence and a pointer to an expression for the part that has been parsed so far. Note that "x" is a perfectly valid expression: As such, "binoprhs" is allowed to be empty, in which case it returns the expression that is passed into it. In our example above, the code passes the expression for "a" into ParseBinOpRHS and the current token is "+".

The precedence value passed into ParseBinOpRHS indicates the *minimal operator precedence* that the function is allowed to eat. For example, if the current pair stream is [+, x] and ParseBinOpRHS is passed in a precedence of 40, it will not consume any tokens (because the precedence of '+' is only 20). With this in mind, ParseBinOpRHS starts with:

```
/// binoprhs
///   ::= ('+' primary)*
static std::unique_ptr<ExprAST> ParseBinOpRHS(int ExprPrec,
                                              std::unique_ptr<ExprAST> LHS) {
  // If this is a binop, find its precedence.
  while (true) {
    int TokPrec = GetTokPrecedence();

    // If this is a binop that binds at least as tightly as the current binop,
    // consume it, otherwise we are done.
    if (TokPrec < ExprPrec)
      return LHS;
```

This code gets the precedence of the current token and checks to see if if is too low. Because we defined invalid tokens to have a precedence of -1, this check implicitly knows that the pair-stream ends when the token stream runs out of binary operators. If this check succeeds, we know that the token is a binary operator and that it will be included in this expression:

```
// Okay, we know this is a binop.
int BinOp = CurTok;
getNextToken();  // eat binop

// Parse the primary expression after the binary operator.
auto RHS = ParsePrimary();
if (!RHS)
  return nullptr;
```

As such, this code eats (and remembers) the binary operator and then parses the primary expression that follows. This builds up the whole pair, the first of which is [+, b] for the running example.

Now that we parsed the left-hand side of an expression and one pair of the RHS sequence, we have to decide which way the expression associates. In particular, we could have "(a+b) binop unparsed"

or “a + (b binop unparsed)”. To determine this, we look ahead at “binop” to determine its precedence and compare it to BinOp’s precedence (which is ‘+’ in this case):

```
// If BinOp binds less tightly with RHS than the operator after RHS, let
// the pending operator take RHS as its LHS.
int NextPrec = GetTokPrecedence();
if (TokPrec < NextPrec) {
```

If the precedence of the binop to the right of “RHS” is lower or equal to the precedence of our current operator, then we know that the parentheses associate as “(a+b) binop ...”. In our example, the current operator is “+” and the next operator is “+”, we know that they have the same precedence. In this case we’ll create the AST node for “a+b”, and then continue parsing:

```
      ... if body omitted ...
    }

    // Merge LHS/RHS.
    LHS = std::make_unique<BinaryExprAST>(BinOp, std::move(LHS),
                                          std::move(RHS));
  }  // loop around to the top of the while loop.
}
```

In our example above, this will turn “a+b+” into “(a+b)” and execute the next iteration of the loop, with “+” as the current token. The code above will eat, remember, and parse “(c+d)” as the primary expression, which makes the current pair equal to [+, (c+d)]. It will then evaluate the ‘if’ conditional above with “*” as the binop to the right of the primary. In this case, the precedence of “*” is higher than the precedence of “+” so the if condition will be entered.

The critical question left here is “how can the if condition parse the right hand side in full”? In particular, to build the AST correctly for our example, it needs to get all of “(c+d)*e*f” as the RHS expression variable. The code to do this is surprisingly simple (code from the above two blocks duplicated for context):

```
    // If BinOp binds less tightly with RHS than the operator after RHS, let
    // the pending operator take RHS as its LHS.
    int NextPrec = GetTokPrecedence();
    if (TokPrec < NextPrec) {
      RHS = ParseBinOpRHS(TokPrec+1, std::move(RHS));
      if (!RHS)
        return nullptr;
    }
    // Merge LHS/RHS.
    LHS = std::make_unique<BinaryExprAST>(BinOp, std::move(LHS),
                                          std::move(RHS));
  }  // loop around to the top of the while loop.
}
```

At this point, we know that the binary operator to the RHS of our primary has higher precedence than the binop we are currently parsing. As such, we know that any sequence of pairs whose operators are all higher precedence than “+” should be parsed together and returned as “RHS”. To

do this, we recursively invoke the ParseBinOpRHS function specifying "TokPrec+1" as the minimum precedence required for it to continue. In our example above, this will cause it to return the AST node for "(c+d)*e*f" as RHS, which is then set as the RHS of the '+' expression.

Finally, on the next iteration of the while loop, the "+g" piece is parsed and added to the AST. With this little bit of code (14 non-trivial lines), we correctly handle fully general binary expression parsing in a very elegant way. This was a whirlwind tour of this code, and it is somewhat subtle. I recommend running through it with a few tough examples to see how it works.

This wraps up handling of expressions. At this point, we can point the parser at an arbitrary token stream and build an expression from it, stopping at the first token that is not part of the expression. Next up we need to handle function definitions, etc.

2.6. Parsing the Rest ¶

The next thing missing is handling of function prototypes. In Kaleidoscope, these are used both for 'extern' function declarations as well as function body definitions. The code to do this is straight-forward and not very interesting (once you've survived expressions):

```
/// prototype
///   ::= id '(' id* ')'
static std::unique_ptr<PrototypeAST> ParsePrototype() {
  if (CurTok != tok_identifier)
    return LogErrorP("Expected function name in prototype");

  std::string FnName = IdentifierStr;
  getNextToken();

  if (CurTok != '(')
    return LogErrorP("Expected '(' in prototype");

  // Read the list of argument names.
  std::vector<std::string> ArgNames;
  while (getNextToken() == tok_identifier)
    ArgNames.push_back(IdentifierStr);
  if (CurTok != ')')
    return LogErrorP("Expected ')' in prototype");

  // success.
  getNextToken();  // eat ')'.

  return std::make_unique<PrototypeAST>(FnName, std::move(ArgNames));
}
```

Given this, a function definition is very simple, just a prototype plus an expression to implement the body:

```
/// definition ::= 'def' prototype expression
static std::unique_ptr<FunctionAST> ParseDefinition() {
  getNextToken();  // eat def.
  auto Proto = ParsePrototype();
  if (!Proto) return nullptr;
```

```
  if (auto E = ParseExpression())
    return std::make_unique<FunctionAST>(std::move(Proto), std::move(E));
  return nullptr;
}
```

In addition, we support 'extern' to declare functions like 'sin' and 'cos' as well as to support forward declaration of user functions. These 'extern's are just prototypes with no body:

```
/// external ::= 'extern' prototype
static std::unique_ptr<PrototypeAST> ParseExtern() {
  getNextToken();  // eat extern.
  return ParsePrototype();
}
```

Finally, we'll also let the user type in arbitrary top-level expressions and evaluate them on the fly. We will handle this by defining anonymous nullary (zero argument) functions for them:

```
/// toplevelexpr ::= expression
static std::unique_ptr<FunctionAST> ParseTopLevelExpr() {
  if (auto E = ParseExpression()) {
    // Make an anonymous proto.
    auto Proto = std::make_unique<PrototypeAST>("", std::vector<std::string>());
    return std::make_unique<FunctionAST>(std::move(Proto), std::move(E));
  }
  return nullptr;
}
```

Now that we have all the pieces, let's build a little driver that will let us actually *execute* this code we've built!

2.7. The Driver ¶

The driver for this simply invokes all of the parsing pieces with a top-level dispatch loop. There isn't much interesting here, so I'll just include the top-level loop. See below for full code in the "Top-Level Parsing" section.

```
/// top ::= definition | external | expression | ';'
static void MainLoop() {
  while (true) {
    fprintf(stderr, "ready> ");
    switch (CurTok) {
    case tok_eof:
      return;
    case ';': // ignore top-level semicolons.
      getNextToken();
      break;
    case tok_def:
      HandleDefinition();
      break;
    case tok_extern:
      HandleExtern();
      break;
```

```
    default:
      HandleTopLevelExpression();
      break;
    }
  }
}
```

The most interesting part of this is that we ignore top-level semicolons. Why is this, you ask? The basic reason is that if you type "4 + 5" at the command line, the parser doesn't know whether that is the end of what you will type or not. For example, on the next line you could type "def foo..." in which case 4+5 is the end of a top-level expression. Alternatively you could type "* 6", which would continue the expression. Having top-level semicolons allows you to type "4+5;", and the parser will know you are done.

2.8. Conclusions ¶

With just under 400 lines of commented code (240 lines of non-comment, non-blank code), we fully defined our minimal language, including a lexer, parser, and AST builder. With this done, the executable will validate Kaleidoscope code and tell us if it is grammatically invalid. For example, here is a sample interaction:

```
$ ./a.out
ready> def foo(x y) x+foo(y, 4.0);
Parsed a function definition.
ready> def foo(x y) x+y y;
Parsed a function definition.
Parsed a top-level expr
ready> def foo(x y) x+y );
Parsed a function definition.
Error: unknown token when expecting an expression
ready> extern sin(a);
ready> Parsed an extern
ready> ^D
$
```

There is a lot of room for extension here. You can define new AST nodes, extend the language in many ways, etc. In the next installment, we will describe how to generate LLVM Intermediate Representation (IR) from the AST.

2.9. Full Code Listing ¶

Here is the complete code listing for our running example.

```
# Compile
clang++ -g -O3 toy.cpp
# Run
./a.out
```

Here is the code:

```cpp
#include <cctype>
#include <cstdio>
#include <cstdlib>
#include <map>
#include <memory>
#include <string>
#include <utility>
#include <vector>

//===----------------------------------------------------------------------===//
// Lexer
//===----------------------------------------------------------------------===//

// The lexer returns tokens [0-255] if it is an unknown character, otherwise one
// of these for known things.
enum Token {
  tok_eof = -1,

  // commands
  tok_def = -2,
  tok_extern = -3,

  // primary
  tok_identifier = -4,
  tok_number = -5
};

static std::string IdentifierStr; // Filled in if tok_identifier
static double NumVal;             // Filled in if tok_number

/// gettok - Return the next token from standard input.
static int gettok() {
  static int LastChar = ' ';

  // Skip any whitespace.
  while (isspace(LastChar))
    LastChar = getchar();

  if (isalpha(LastChar)) { // identifier: [a-zA-Z][a-zA-Z0-9]*
    IdentifierStr = LastChar;
    while (isalnum((LastChar = getchar())))
      IdentifierStr += LastChar;

    if (IdentifierStr == "def")
      return tok_def;
    if (IdentifierStr == "extern")
      return tok_extern;
    return tok_identifier;
  }

  if (isdigit(LastChar) || LastChar == '.') { // Number: [0-9.]+
    std::string NumStr;
    do {
      NumStr += LastChar;
      LastChar = getchar();
    } while (isdigit(LastChar) || LastChar == '.');
```

```
    NumVal = strtod(NumStr.c_str(), nullptr);
    return tok_number;
  }

  if (LastChar == '#') {
    // Comment until end of line.
    do
      LastChar = getchar();
    while (LastChar != EOF && LastChar != '\n' && LastChar != '\r');

    if (LastChar != EOF)
      return gettok();
  }

  // Check for end of file.  Don't eat the EOF.
  if (LastChar == EOF)
    return tok_eof;

  // Otherwise, just return the character as its ascii value.
  int ThisChar = LastChar;
  LastChar = getchar();
  return ThisChar;
}

//===----------------------------------------------------------------------===//

Next: Implementing Code Generation to LLVM IR

3. Kaleidoscope: Code generation to LLVM IR ¶

3.1. Chapter 3 Introduction ¶

Welcome to Chapter 3 of the "Implementing a language with LLVM" tutorial. This chapter shows you how to transform the Abstract Syntax Tree, built in Chapter 2, into LLVM IR. This will teach you a little bit about how LLVM does things, as well as demonstrate how easy it is to use. It's much more work to build a lexer and parser than it is to generate LLVM IR code. :)

Please note: the code in this chapter and later require LLVM 3.7 or later. LLVM 3.6 and before will not work with it. Also note that you need to use a version of this tutorial that matches your LLVM release: If you are using an official LLVM release, use the version of the documentation included with your release or on the llvm.org releases page.

3.2. Code Generation Setup ¶

In order to generate LLVM IR, we want some simple setup to get started. First we define virtual code generation (codegen) methods in each AST class:

```
/// ExprAST - Base class for all expression nodes.
class ExprAST {
public:
  virtual ~ExprAST() = default;
  virtual Value *codegen() = 0;
};

/// NumberExprAST - Expression class for numeric literals like "1.0".
class NumberExprAST : public ExprAST {
  double Val;

public:
  NumberExprAST(double Val) : Val(Val) {}
  Value *codegen() override;
};
...
```

The codegen() method says to emit IR for that AST node along with all the things it depends on, and they all return an LLVM Value object. "Value" is the class used to represent a "Static Single Assignment (SSA) register" or "SSA value" in LLVM. The most distinct aspect of SSA values is that their value is computed as the related instruction executes, and it does not get a new value until (and if) the instruction re-executes. In other words, there is no way to "change" an SSA value. For more information, please read up on Static Single Assignment – the concepts are really quite natural once you grok them.

Note that instead of adding virtual methods to the ExprAST class hierarchy, it could also make sense to use a visitor pattern or some other way to model this. Again, this tutorial won't dwell on

good software engineering practices: for our purposes, adding a virtual method is simplest.

The second thing we want is a "LogError" method like we used for the parser, which will be used to report errors found during code generation (for example, use of an undeclared parameter):

```
static std::unique_ptr<LLVMContext> TheContext;
            static std::unique_ptr<IRBuilder<>> Builder;
            static std::unique_ptr<Module> TheModule;
            static std::map<std::string, Value *> NamedValues;

            Value *LogErrorV(const char *Str) {
              LogError(Str);
              return nullptr;
            }
```

The static variables will be used during code generation. `TheContext` is an opaque object that owns a lot of core LLVM data structures, such as the type and constant value tables. We don't need to understand it in detail, we just need a single instance to pass into APIs that require it.

The `Builder` object is a helper object that makes it easy to generate LLVM instructions. Instances of the IRBuilder class template keep track of the current place to insert instructions and has methods to create new instructions.

`TheModule` is an LLVM construct that contains functions and global variables. In many ways, it is the top-level structure that the LLVM IR uses to contain code. It will own the memory for all of the IR that we generate, which is why the codegen() method returns a raw Value*, rather than a unique_ptr<Value>.

The `NamedValues` map keeps track of which values are defined in the current scope and what their LLVM representation is. (In other words, it is a symbol table for the code). In this form of Kaleidoscope, the only things that can be referenced are function parameters. As such, function parameters will be in this map when generating code for their function body.

With these basics in place, we can start talking about how to generate code for each expression. Note that this assumes that the `Builder` has been set up to generate code *into* something. For now, we'll assume that this has already been done, and we'll just use it to emit code.

3.3. Expression Code Generation ¶

Generating LLVM code for expression nodes is very straightforward: less than 45 lines of commented code for all four of our expression nodes. First we'll do numeric literals:

```
Value *NumberExprAST::codegen() {
              return ConstantFP::get(*TheContext, APFloat(Val));
            }
```

In the LLVM IR, numeric constants are represented with the `ConstantFP` class, which holds the numeric value in an `APFloat` internally (`APFloat` has the capability of holding floating point

constants of Arbitrary Precision). This code basically just creates and returns a `ConstantFP`. Note that in the LLVM IR that constants are all uniqued together and shared. For this reason, the API uses the "foo::get(...)" idiom instead of "new foo(..)" or "foo::Create(..)".

```
Value *VariableExprAST::codegen() {
              // Look this variable up in the function.
              Value *V = NamedValues[Name];
              if (!V)
                LogErrorV("Unknown variable name");
              return V;
            }
```

References to variables are also quite simple using LLVM. In the simple version of Kaleidoscope, we assume that the variable has already been emitted somewhere and its value is available. In practice, the only values that can be in the `NamedValues` map are function arguments. This code simply checks to see that the specified name is in the map (if not, an unknown variable is being referenced) and returns the value for it. In future chapters, we'll add support for loop induction variables in the symbol table, and for local variables.

```
Value *BinaryExprAST::codegen() {
              Value *L = LHS->codegen();
              Value *R = RHS->codegen();
              if (!L || !R)
                return nullptr;

              switch (Op) {
              case '+':
                return Builder->CreateFAdd(L, R, "addtmp");
              case '-':
                return Builder->CreateFSub(L, R, "subtmp");
              case '*':
                return Builder->CreateFMul(L, R, "multmp");
              case '<':
                L = Builder->CreateFCmpULT(L, R, "cmptmp");
                // Convert bool 0/1 to double 0.0 or 1.0
                return Builder->CreateUIToFP(L, Type::getDoubleTy(*TheContext),
                                             "booltmp");
              default:
                return LogErrorV("invalid binary operator");
              }
            }
```

Binary operators start to get more interesting. The basic idea here is that we recursively emit code for the left-hand side of the expression, then the right-hand side, then we compute the result of the binary expression. In this code, we do a simple switch on the opcode to create the right LLVM instruction.

In the example above, the LLVM builder class is starting to show its value. IRBuilder knows where to insert the newly created instruction, all you have to do is specify what instruction to create (e.g.

with `CreateFAdd`), which operands to use (L and R here) and optionally provide a name for the generated instruction.

One nice thing about LLVM is that the name is just a hint. For instance, if the code above emits multiple "addtmp" variables, LLVM will automatically provide each one with an increasing, unique numeric suffix. Local value names for instructions are purely optional, but it makes it much easier to read the IR dumps.

LLVM instructions are constrained by strict rules: for example, the Left and Right operands of an add instruction must have the same type, and the result type of the add must match the operand types. Because all values in Kaleidoscope are doubles, this makes for very simple code for add, sub and mul.

On the other hand, LLVM specifies that the fcmp instruction always returns an 'i1' value (a one bit integer). The problem with this is that Kaleidoscope wants the value to be a 0.0 or 1.0 value. In order to get these semantics, we combine the fcmp instruction with a uitofp instruction. This instruction converts its input integer into a floating point value by treating the input as an unsigned value. In contrast, if we used the sitofp instruction, the Kaleidoscope '<' operator would return 0.0 and -1.0, depending on the input value.

```
Value *CallExprAST::codegen() {
              // Look up the name in the global module table.
              Function *CalleeF = TheModule->getFunction(Callee);
              if (!CalleeF)
                return LogErrorV("Unknown function referenced");

              // If argument mismatch error.
              if (CalleeF->arg_size() != Args.size())
                return LogErrorV("Incorrect # arguments passed");

              std::vector<Value *> ArgsV;
              for (unsigned i = 0, e = Args.size(); i != e; ++i) {
                ArgsV.push_back(Args[i]->codegen());
                if (!ArgsV.back())
                  return nullptr;
              }

              return Builder->CreateCall(CalleeF, ArgsV, "calltmp");
            }
```

Code generation for function calls is quite straightforward with LLVM. The code above initially does a function name lookup in the LLVM Module's symbol table. Recall that the LLVM Module is the container that holds the functions we are JIT'ing. By giving each function the same name as what the user specifies, we can use the LLVM symbol table to resolve function names for us.

Once we have the function to call, we recursively codegen each argument that is to be passed in, and create an LLVM call instruction. Note that LLVM uses the native C calling conventions by default, allowing these calls to also call into standard library functions like "sin" and "cos", with no additional effort.

This wraps up our handling of the four basic expressions that we have so far in Kaleidoscope. Feel free to go in and add some more. For example, by browsing the LLVM language reference you'll find several other interesting instructions that are really easy to plug into our basic framework.

3.4. Function Code Generation ¶

Code generation for prototypes and functions must handle a number of details, which make their code less beautiful than expression code generation, but allows us to illustrate some important points. First, let's talk about code generation for prototypes: they are used both for function bodies and external function declarations. The code starts with:

```
Function *PrototypeAST::codegen() {
              // Make the function type:  double(double,double) etc.
              std::vector<Type*> Doubles(Args.size(),
                                         Type::getDoubleTy(*TheContext));
              FunctionType *FT =
                FunctionType::get(Type::getDoubleTy(*TheContext), Doubles, false);

              Function *F =
                Function::Create(FT, Function::ExternalLinkage, Name, TheModule.get());
```

This code packs a lot of power into a few lines. Note first that this function returns a "Function*" instead of a "Value*". Because a "prototype" really talks about the external interface for a function (not the value computed by an expression), it makes sense for it to return the LLVM Function it corresponds to when codegen'd.

The call to `FunctionType::get` creates the `FunctionType` that should be used for a given Prototype. Since all function arguments in Kaleidoscope are of type double, the first line creates a vector of "N" LLVM double types. It then uses the `Functiontype::get` method to create a function type that takes "N" doubles as arguments, returns one double as a result, and that is not vararg (the false parameter indicates this). Note that Types in LLVM are uniqued just like Constants are, so you don't "new" a type, you "get" it.

The final line above actually creates the IR Function corresponding to the Prototype. This indicates the type, linkage and name to use, as well as which module to insert into. "external linkage" means that the function may be defined outside the current module and/or that it is callable by functions outside the module. The Name passed in is the name the user specified: since "`TheModule`" is specified, this name is registered in "`TheModule`"s symbol table.

```
// Set names for all arguments.
              unsigned Idx = 0;
              for (auto &Arg : F->args())
                Arg.setName(Args[Idx++]);

              return F;
```

Finally, we set the name of each of the function's arguments according to the names given in the Prototype. This step isn't strictly necessary, but keeping the names consistent makes the IR more readable, and allows subsequent code to refer directly to the arguments for their names, rather than having to look up them up in the Prototype AST.

At this point we have a function prototype with no body. This is how LLVM IR represents function declarations. For extern statements in Kaleidoscope, this is as far as we need to go. For function definitions however, we need to codegen and attach a function body.

```
Function *FunctionAST::codegen() {
                // First, check for an existing function from a previous 'extern' declaration.
              Function *TheFunction = TheModule->getFunction(Proto->getName());

              if (!TheFunction)
                TheFunction = Proto->codegen();

              if (!TheFunction)
                return nullptr;

              if (!TheFunction->empty())
                return (Function*)LogErrorV("Function cannot be redefined.");
```

For function definitions, we start by searching TheModule's symbol table for an existing version of this function, in case one has already been created using an 'extern' statement. If Module::getFunction returns null then no previous version exists, so we'll codegen one from the Prototype. In either case, we want to assert that the function is empty (i.e. has no body yet) before we start.

```
// Create a new basic block to start insertion into.
            BasicBlock *BB = BasicBlock::Create(*TheContext, "entry", TheFunction);
            Builder->SetInsertPoint(BB);

            // Record the function arguments in the NamedValues map.
            NamedValues.clear();
            for (auto &Arg : TheFunction->args())
              NamedValues[std::string(Arg.getName())] = &Arg;
```

Now we get to the point where the `Builder` is set up. The first line creates a new basic block (named "entry"), which is inserted into `TheFunction`. The second line then tells the builder that new instructions should be inserted into the end of the new basic block. Basic blocks in LLVM are an important part of functions that define the Control Flow Graph. Since we don't have any control flow, our functions will only contain one block at this point. We'll fix this in Chapter 5 :).

Next we add the function arguments to the NamedValues map (after first clearing it out) so that they're accessible to `VariableExprAST` nodes.

```
if (Value *RetVal = Body->codegen()) {
              // Finish off the function.
```

```
    Builder->CreateRet(RetVal);

    // Validate the generated code, checking for consistency.
    verifyFunction(*TheFunction);

    return TheFunction;
  }
```

Once the insertion point has been set up and the NamedValues map populated, we call the `codegen()` method for the root expression of the function. If no error happens, this emits code to compute the expression into the entry block and returns the value that was computed. Assuming no error, we then create an LLVM ret instruction, which completes the function. Once the function is built, we call `verifyFunction`, which is provided by LLVM. This function does a variety of consistency checks on the generated code, to determine if our compiler is doing everything right. Using this is important: it can catch a lot of bugs. Once the function is finished and validated, we return it.

```
  // Error reading body, remove function.
    TheFunction->eraseFromParent();
    return nullptr;
  }
```

The only piece left here is handling of the error case. For simplicity, we handle this by merely deleting the function we produced with the `eraseFromParent` method. This allows the user to redefine a function that they incorrectly typed in before: if we didn't delete it, it would live in the symbol table, with a body, preventing future redefinition.

This code does have a bug, though: If the `FunctionAST::codegen()` method finds an existing IR Function, it does not validate its signature against the definition's own prototype. This means that an earlier 'extern' declaration will take precedence over the function definition's signature, which can cause codegen to fail, for instance if the function arguments are named differently. There are a number of ways to fix this bug, see what you can come up with! Here is a testcase:

```
extern foo(a);     # ok, defines foo.
def foo(b) b;      # Error: Unknown variable name. (decl using 'a' takes precedence
```

3.5. Driver Changes and Closing Thoughts ¶

For now, code generation to LLVM doesn't really get us much, except that we can look at the pretty IR calls. The sample code inserts calls to codegen into the "`HandleDefinition`", "`HandleExtern`" etc functions, and then dumps out the LLVM IR. This gives a nice way to look at the LLVM IR for simple functions. For example:

```
ready> 4+5;
Read top-level expression:
define double @0() {
```

```
            entry:
              ret double 9.000000e+00
            }
```

Note how the parser turns the top-level expression into anonymous functions for us. This will be handy when we add JIT support in the next chapter. Also note that the code is very literally transcribed, no optimizations are being performed except simple constant folding done by IRBuilder. We will add optimizations explicitly in the next chapter.

```
ready> def foo(a b) a*a + 2*a*b + b*b;
            Read function definition:
            define double @foo(double %a, double %b) {
            entry:
              %multmp = fmul double %a, %a
              %multmp1 = fmul double 2.000000e+00, %a
              %multmp2 = fmul double %multmp1, %b
              %addtmp = fadd double %multmp, %multmp2
              %multmp3 = fmul double %b, %b
              %addtmp4 = fadd double %addtmp, %multmp3
              ret double %addtmp4
            }
```

This shows some simple arithmetic. Notice the striking similarity to the LLVM builder calls that we use to create the instructions.

```
ready> def bar(a) foo(a, 4.0) + bar(31337);
            Read function definition:
            define double @bar(double %a) {
            entry:
              %calltmp = call double @foo(double %a, double 4.000000e+00)
              %calltmp1 = call double @bar(double 3.133700e+04)
              %addtmp = fadd double %calltmp, %calltmp1
              ret double %addtmp
            }
```

This shows some function calls. Note that this function will take a long time to execute if you call it. In the future we'll add conditional control flow to actually make recursion useful :).

```
ready> extern cos(x);
            Read extern:
            declare double @cos(double)

            ready> cos(1.234);
            Read top-level expression:
            define double @1() {
            entry:
              %calltmp = call double @cos(double 1.234000e+00)
              ret double %calltmp
            }
```

This shows an extern for the libm “cos” function, and a call to it.

```
ready> ^D
            ; ModuleID = 'my cool jit'

            define double @0() {
            entry:
              %addtmp = fadd double 4.000000e+00, 5.000000e+00
              ret double %addtmp
            }

            define double @foo(double %a, double %b) {
            entry:
              %multmp = fmul double %a, %a
              %multmp1 = fmul double 2.000000e+00, %a
              %multmp2 = fmul double %multmp1, %b
              %addtmp = fadd double %multmp, %multmp2
              %multmp3 = fmul double %b, %b
              %addtmp4 = fadd double %addtmp, %multmp3
              ret double %addtmp4
            }

            define double @bar(double %a) {
            entry:
              %calltmp = call double @foo(double %a, double 4.000000e+00)
              %calltmp1 = call double @bar(double 3.133700e+04)
              %addtmp = fadd double %calltmp, %calltmp1
              ret double %addtmp
            }

            declare double @cos(double)

            define double @1() {
            entry:
              %calltmp = call double @cos(double 1.234000e+00)
              ret double %calltmp
            }
```

When you quit the current demo (by sending an EOF via CTRL+D on Linux or CTRL+Z and ENTER on Windows), it dumps out the IR for the entire module generated. Here you can see the big picture with all the functions referencing each other.

This wraps up the third chapter of the Kaleidoscope tutorial. Up next, we’ll describe how to add JIT codegen and optimizer support to this so we can actually start running code!

3.6. Full Code Listing ¶

Here is the complete code listing for our running example, enhanced with the LLVM code generator. Because this uses the LLVM libraries, we need to link them in. To do this, we use the llvm-config tool to inform our makefile/command line about which options to use:

```
# Compile
            clang++ -g -O3 toy.cpp `llvm-config --cxxflags --ldflags --system-libs --libs core
```

```
# Run
./toy
```

Here is the code:

```
#include "llvm/ADT/APFloat.h"
#include "llvm/ADT/STLExtras.h"
#include "llvm/IR/BasicBlock.h"
#include "llvm/IR/Constants.h"
#include "llvm/IR/DerivedTypes.h"
#include "llvm/IR/Function.h"
#include "llvm/IR/IRBuilder.h"
#include "llvm/IR/LLVMContext.h"
#include "llvm/IR/Module.h"
#include "llvm/IR/Type.h"
#include "llvm/IR/Verifier.h"
#include <algorithm>
#include <cctype>
#include <cstdio>
#include <cstdlib>
#include <map>
#include <memory>
#include <string>
#include <vector>

using namespace llvm;

//===----------------------------------------------------------------------===//
// Lexer
//===----------------------------------------------------------------------===//

// The lexer returns tokens [0-255] if it is an unknown character, otherwise one
// of these for known things.
enum Token {
  tok_eof = -1,

Next: Adding JIT and Optimizer Support

4. Kaleidoscope: Adding JIT and Optimizer Support ¶

4.1. Chapter 4 Introduction ¶

Welcome to Chapter 4 of the "Implementing a language with LLVM" tutorial. Chapters 1-3 described the implementation of a simple language and added support for generating LLVM IR. This chapter describes two new techniques: adding optimizer support to your language, and adding JIT compiler support. These additions will demonstrate how to get nice, efficient code for the Kaleidoscope language.

4.2. Trivial Constant Folding ¶

Our demonstration for Chapter 3 is elegant and easy to extend. Unfortunately, it does not produce wonderful code. The IRBuilder, however, does give us obvious optimizations when compiling simple code:

```
ready> def test(x) 1+2+x;
            Read function definition:
            define double @test(double %x) {
            entry:
                    %addtmp = fadd double 3.000000e+00, %x
                    ret double %addtmp
            }
```

This code is not a literal transcription of the AST built by parsing the input. That would be:

```
ready> def test(x) 1+2+x;
            Read function definition:
            define double @test(double %x) {
            entry:
                    %addtmp = fadd double 2.000000e+00, 1.000000e+00
                    %addtmp1 = fadd double %addtmp, %x
                    ret double %addtmp1
            }
```

Constant folding, as seen above, in particular, is a very common and very important optimization: so much so that many language implementors implement constant folding support in their AST representation.

With LLVM, you don't need this support in the AST. Since all calls to build LLVM IR go through the LLVM IR builder, the builder itself checked to see if there was a constant folding opportunity when you call it. If so, it just does the constant fold and return the constant instead of creating an instruction.

Well, that was easy :). In practice, we recommend always using `IRBuilder` when generating code like this. It has no "syntactic overhead" for its use (you don't have to uglify your compiler with constant checks everywhere) and it can dramatically reduce the amount of LLVM IR that is generated in some cases (particular for languages with a macro preprocessor or that use a lot of constants).

On the other hand, the `IRBuilder` is limited by the fact that it does all of its analysis inline with the code as it is built. If you take a slightly more complex example:

```
ready> def test(x) (1+2+x)*(x+(1+2));
            ready> Read function definition:
            define double @test(double %x) {
            entry:
                    %addtmp = fadd double 3.000000e+00, %x
                    %addtmp1 = fadd double %x, 3.000000e+00
                    %multtmp = fmul double %addtmp, %addtmp1
                    ret double %multtmp
            }
```

In this case, the LHS and RHS of the multiplication are the same value. We'd really like to see this generate "`tmp = x+3; result = tmp*tmp;`" instead of computing "`x+3`" twice.

Unfortunately, no amount of local analysis will be able to detect and correct this. This requires two transformations: reassociation of expressions (to make the add's lexically identical) and Common Subexpression Elimination (CSE) to delete the redundant add instruction. Fortunately, LLVM provides a broad range of optimizations that you can use, in the form of "passes".

4.3. LLVM Optimization Passes ¶

LLVM provides many optimization passes, which do many different sorts of things and have different tradeoffs. Unlike other systems, LLVM doesn't hold to the mistaken notion that one set of optimizations is right for all languages and for all situations. LLVM allows a compiler implementor to make complete decisions about what optimizations to use, in which order, and in what situation.

As a concrete example, LLVM supports both "whole module" passes, which look across as large of body of code as they can (often a whole file, but if run at link time, this can be a substantial portion of the whole program). It also supports and includes "per-function" passes which just operate on a single function at a time, without looking at other functions. For more information on passes and how they are run, see the How to Write a Pass document and the List of LLVM Passes.

For Kaleidoscope, we are currently generating functions on the fly, one at a time, as the user types them in. We aren't shooting for the ultimate optimization experience in this setting, but we also want to catch the easy and quick stuff where possible. As such, we will choose to run a few per-function optimizations as the user types the function in. If we wanted to make a "static Kaleidoscope compiler", we would use exactly the code we have now, except that we would defer running the optimizer until the entire file has been parsed.

In addition to the distinction between function and module passes, passes can be divided into transform and analysis passes. Transform passes mutate the IR, and analysis passes compute information that other passes can use. In order to add a transform pass, all analysis passes it depends upon must be registered in advance.

In order to get per-function optimizations going, we need to set up a FunctionPassManager to hold and organize the LLVM optimizations that we want to run. Once we have that, we can add a set of optimizations to run. We'll need a new FunctionPassManager for each module that we want to optimize, so we'll add to a function created in the previous chapter (`InitializeModule()`):

```
void InitializeModuleAndManagers(void) {
              // Open a new context and module.
              TheContext = std::make_unique<LLVMContext>();
              TheModule = std::make_unique<Module>("KaleidoscopeJIT", *TheContext);
              TheModule->setDataLayout(TheJIT->getDataLayout());

              // Create a new builder for the module.
              Builder = std::make_unique<IRBuilder<>>(*TheContext);

              // Create new pass and analysis managers.
              TheFPM = std::make_unique<FunctionPassManager>();
              TheLAM = std::make_unique<LoopAnalysisManager>();
              TheFAM = std::make_unique<FunctionAnalysisManager>();
              TheCGAM = std::make_unique<CGSCCAnalysisManager>();
              TheMAM = std::make_unique<ModuleAnalysisManager>();
              ThePIC = std::make_unique<PassInstrumentationCallbacks>();
              TheSI = std::make_unique<StandardInstrumentations>(*TheContext,
                                                                 /*DebugLogging*/ true);
              TheSI->registerCallbacks(*ThePIC, TheMAM.get());
              ...
```

After initializing the global module `TheModule` and the FunctionPassManager, we need to initialize other parts of the framework. The four AnalysisManagers allow us to add analysis passes that run across the four levels of the IR hierarchy. PassInstrumentationCallbacks and StandardInstrumentations are required for the pass instrumentation framework, which allows developers to customize what happens between passes.

Once these managers are set up, we use a series of "addPass" calls to add a bunch of LLVM transform passes:

```
// Add transform passes.
            // Do simple "peephole" optimizations and bit-twiddling optzns.
            TheFPM->addPass(InstCombinePass());
```

```
            // Reassociate expressions.
            TheFPM->addPass(ReassociatePass());
            // Eliminate Common SubExpressions.
            TheFPM->addPass(GVNPass());
            // Simplify the control flow graph (deleting unreachable blocks, etc).
            TheFPM->addPass(SimplifyCFGPass());
```

In this case, we choose to add four optimization passes. The passes we choose here are a pretty standard set of "cleanup" optimizations that are useful for a wide variety of code. I won't delve into what they do but, believe me, they are a good starting place :).

Next, we register the analysis passes used by the transform passes.

```
  // Register analysis passes used in these transform passes.
            PassBuilder PB;
            PB.registerModuleAnalyses(*TheMAM);
            PB.registerFunctionAnalyses(*TheFAM);
            PB.crossRegisterProxies(*TheLAM, *TheFAM, *TheCGAM, *TheMAM);
          }
```

Once the PassManager is set up, we need to make use of it. We do this by running it after our newly created function is constructed (in `FunctionAST::codegen()`), but before it is returned to the client:

```
if (Value *RetVal = Body->codegen()) {
            // Finish off the function.
            Builder.CreateRet(RetVal);

            // Validate the generated code, checking for consistency.
            verifyFunction(*TheFunction);

            // Optimize the function.
            TheFPM->run(*TheFunction, *TheFAM);

            return TheFunction;
          }
```

As you can see, this is pretty straightforward. The `FunctionPassManager` optimizes and updates the LLVM Function* in place, improving (hopefully) its body. With this in place, we can try our test above again:

```
ready> def test(x) (1+2+x)*(x+(1+2));
           ready> Read function definition:
           define double @test(double %x) {
           entry:
                   %addtmp = fadd double %x, 3.000000e+00
                   %multmp = fmul double %addtmp, %addtmp
                   ret double %multmp
```

```
}
```

As expected, we now get our nicely optimized code, saving a floating point add instruction from every execution of this function.

LLVM provides a wide variety of optimizations that can be used in certain circumstances. Some documentation about the various passes is available, but it isn't very complete. Another good source of ideas can come from looking at the passes that `Clang` runs to get started. The "`opt`" tool allows you to experiment with passes from the command line, so you can see if they do anything.

Now that we have reasonable code coming out of our front-end, let's talk about executing it!

4.4. Adding a JIT Compiler ¶

Code that is available in LLVM IR can have a wide variety of tools applied to it. For example, you can run optimizations on it (as we did above), you can dump it out in textual or binary forms, you can compile the code to an assembly file (.s) for some target, or you can JIT compile it. The nice thing about the LLVM IR representation is that it is the "common currency" between many different parts of the compiler.

In this section, we'll add JIT compiler support to our interpreter. The basic idea that we want for Kaleidoscope is to have the user enter function bodies as they do now, but immediately evaluate the top-level expressions they type in. For example, if they type in "1 + 2;", we should evaluate and print out 3. If they define a function, they should be able to call it from the command line.

In order to do this, we first prepare the environment to create code for the current native target and declare and initialize the JIT. This is done by calling some `InitializeNativeTarget\*` functions and adding a global variable `TheJIT`, and initializing it in `main`:

```
static std::unique_ptr<KaleidoscopeJIT> TheJIT;
            ...
            int main() {
              InitializeNativeTarget();
              InitializeNativeTargetAsmPrinter();
              InitializeNativeTargetAsmParser();

              // Install standard binary operators.
              // 1 is lowest precedence.
              BinopPrecedence['<'] = 10;
              BinopPrecedence['+'] = 20;
              BinopPrecedence['-'] = 20;
              BinopPrecedence['*'] = 40; // highest.

              // Prime the first token.
              fprintf(stderr, "ready> ");
              getNextToken();

              TheJIT = std::make_unique<KaleidoscopeJIT>();

              // Run the main "interpreter loop" now.
              MainLoop();
```

```
      return 0;
    }
```

We also need to setup the data layout for the JIT:

```
void InitializeModuleAndPassManager(void) {
    // Open a new context and module.
    TheContext = std::make_unique<LLVMContext>();
    TheModule = std::make_unique<Module>("my cool jit", TheContext);
    TheModule->setDataLayout(TheJIT->getDataLayout());

    // Create a new builder for the module.
    Builder = std::make_unique<IRBuilder<>>(*TheContext);

    // Create a new pass manager attached to it.
    TheFPM = std::make_unique<legacy::FunctionPassManager>(TheModule.get());
    ...
```

The KaleidoscopeJIT class is a simple JIT built specifically for these tutorials, available inside the LLVM source code at llvm-src/examples/Kaleidoscope/include/KaleidoscopeJIT.h. In later chapters we will look at how it works and extend it with new features, but for now we will take it as given. Its API is very simple: `addModule` adds an LLVM IR module to the JIT, making its functions available for execution (with its memory managed by a `ResourceTracker`); and `lookup` allows us to look up pointers to the compiled code.

We can take this simple API and change our code that parses top-level expressions to look like this:

```
static ExitOnError ExitOnErr;
...
static void HandleTopLevelExpression() {
  // Evaluate a top-level expression into an anonymous function.
  if (auto FnAST = ParseTopLevelExpr()) {
    if (FnAST->codegen()) {
      // Create a ResourceTracker to track JIT'd memory allocated to our
      // anonymous expression -- that way we can free it after executing.
      auto RT = TheJIT->getMainJITDylib().createResourceTracker();

      auto TSM = ThreadSafeModule(std::move(TheModule), std::move(TheContext));
      ExitOnErr(TheJIT->addModule(std::move(TSM), RT));
      InitializeModuleAndPassManager();

      // Search the JIT for the __anon_expr symbol.
      auto ExprSymbol = ExitOnErr(TheJIT->lookup("__anon_expr"));
      assert(ExprSymbol && "Function not found");

      // Get the symbol's address and cast it to the right type (takes no
      // arguments, returns a double) so we can call it as a native function.
      double (*FP)() = ExprSymbol.getAddress().toPtr<double (*)()>();
      fprintf(stderr, "Evaluated to %f\n", FP());
```

```
      // Delete the anonymous expression module from the JIT.
      ExitOnErr(RT->remove());
    }
```

If parsing and codegen succeed, the next step is to add the module containing the top-level expression to the JIT. We do this by calling addModule, which triggers code generation for all the functions in the module, and accepts a `ResourceTracker` which can be used to remove the module from the JIT later. Once the module has been added to the JIT it can no longer be modified, so we also open a new module to hold subsequent code by calling `InitializeModuleAndPassManager()`.

Once we've added the module to the JIT we need to get a pointer to the final generated code. We do this by calling the JIT's `lookup` method, and passing the name of the top-level expression function: `__anon_expr`. Since we just added this function, we assert that `lookup` returned a result.

Next, we get the in-memory address of the `__anon_expr` function by calling `getAddress()` on the symbol. Recall that we compile top-level expressions into a self-contained LLVM function that takes no arguments and returns the computed double. Because the LLVM JIT compiler matches the native platform ABI, this means that you can just cast the result pointer to a function pointer of that type and call it directly. This means, there is no difference between JIT compiled code and native machine code that is statically linked into your application.

Finally, since we don't support re-evaluation of top-level expressions, we remove the module from the JIT when we're done to free the associated memory. Recall, however, that the module we created a few lines earlier (via `InitializeModuleAndPassManager`) is still open and waiting for new code to be added.

With just these two changes, let's see how Kaleidoscope works now!

```
ready> 4+5;
            Read top-level expression:
            define double @0() {
            entry:
              ret double 9.000000e+00
            }

            Evaluated to 9.000000
```

Well this looks like it is basically working. The dump of the function shows the "no argument function that always returns double" that we synthesize for each top-level expression that is typed in. This demonstrates very basic functionality, but can we do more?

```
ready> def testfunc(x y) x + y*2;
            Read function definition:
            define double @testfunc(double %x, double %y) {
            entry:
              %multmp = fmul double %y, 2.000000e+00
```

```
  %addtmp = fadd double %multmp, %x
  ret double %addtmp
}

ready> testfunc(4, 10);
Read top-level expression:
define double @1() {
entry:
  %calltmp = call double @testfunc(double 4.000000e+00, double 1.000000e+01)
  ret double %calltmp
}

Evaluated to 24.000000

ready> testfunc(5, 10);
ready> LLVM ERROR: Program used external function 'testfunc' which could not be res
```

Function definitions and calls also work, but something went very wrong on that last line. The call looks valid, so what happened? As you may have guessed from the API a Module is a unit of allocation for the JIT, and testfunc was part of the same module that contained anonymous expression. When we removed that module from the JIT to free the memory for the anonymous expression, we deleted the definition of `testfunc` along with it. Then, when we tried to call testfunc a second time, the JIT could no longer find it.

The easiest way to fix this is to put the anonymous expression in a separate module from the rest of the function definitions. The JIT will happily resolve function calls across module boundaries, as long as each of the functions called has a prototype, and is added to the JIT before it is called. By putting the anonymous expression in a different module we can delete it without affecting the rest of the functions.

In fact, we're going to go a step further and put every function in its own module. Doing so allows us to exploit a useful property of the KaleidoscopeJIT that will make our environment more REPL-like: Functions can be added to the JIT more than once (unlike a module where every function must have a unique definition). When you look up a symbol in KaleidoscopeJIT it will always return the most recent definition:

```
ready> def foo(x) x + 1;
            Read function definition:
            define double @foo(double %x) {
            entry:
              %addtmp = fadd double %x, 1.000000e+00
              ret double %addtmp
            }

            ready> foo(2);
            Evaluated to 3.000000

            ready> def foo(x) x + 2;
            define double @foo(double %x) {
            entry:
              %addtmp = fadd double %x, 2.000000e+00
```

```
  ret double %addtmp
}

ready> foo(2);
Evaluated to 4.000000
```

To allow each function to live in its own module we'll need a way to re-generate previous function declarations into each new module we open:

```
static std::unique_ptr<KaleidoscopeJIT> TheJIT;

...

Function *getFunction(std::string Name) {
  // First, see if the function has already been added to the current module.
  if (auto *F = TheModule->getFunction(Name))
    return F;

  // If not, check whether we can codegen the declaration from some existing
  // prototype.
  auto FI = FunctionProtos.find(Name);
  if (FI != FunctionProtos.end())
    return FI->second->codegen();

  // If no existing prototype exists, return null.
  return nullptr;
}

...

Value *CallExprAST::codegen() {
  // Look up the name in the global module table.
  Function *CalleeF = getFunction(Callee);

...

Function *FunctionAST::codegen() {
  // Transfer ownership of the prototype to the FunctionProtos map, but keep a
  // reference to it for use below.
  auto &P = *Proto;
  FunctionProtos[Proto->getName()] = std::move(Proto);
  Function *TheFunction = getFunction(P.getName());
  if (!TheFunction)
    return nullptr;
```

To enable this, we'll start by adding a new global, `FunctionProtos`, that holds the most recent prototype for each function. We'll also add a convenience method, `getFunction()`, to replace calls to `TheModule->getFunction()`. Our convenience method searches `TheModule` for an existing function declaration, falling back to generating a new declaration from FunctionProtos if it doesn't find one. In `CallExprAST::codegen()` we just need to replace the call to `TheModule->getFunction()`. In `FunctionAST::codegen()` we need to update the FunctionProtos map

first, then call `getFunction()`. With this done, we can always obtain a function declaration in the current module for any previously declared function.

We also need to update HandleDefinition and HandleExtern:

```
static void HandleDefinition() {
              if (auto FnAST = ParseDefinition()) {
                if (auto *FnIR = FnAST->codegen()) {
                  fprintf(stderr, "Read function definition:");
                  FnIR->print(errs());
                  fprintf(stderr, "\n");
                  ExitOnErr(TheJIT->addModule(
                      ThreadSafeModule(std::move(TheModule), std::move(TheContext))));
                  InitializeModuleAndPassManager();
                }
              } else {
                // Skip token for error recovery.
                 getNextToken();
              }
            }

            static void HandleExtern() {
              if (auto ProtoAST = ParseExtern()) {
                if (auto *FnIR = ProtoAST->codegen()) {
                  fprintf(stderr, "Read extern: ");
                  FnIR->print(errs());
                  fprintf(stderr, "\n");
                  FunctionProtos[ProtoAST->getName()] = std::move(ProtoAST);
                }
              } else {
                // Skip token for error recovery.
                getNextToken();
              }
            }
```

In HandleDefinition, we add two lines to transfer the newly defined function to the JIT and open a new module. In HandleExtern, we just need to add one line to add the prototype to FunctionProtos.

Warning

Duplication of symbols in separate modules is not allowed since LLVM-9. That means you can not redefine function in your Kaleidoscope as its shown below. Just skip this part.

The reason is that the newer OrcV2 JIT APIs are trying to stay very close to the static and dynamic linker rules, including rejecting duplicate symbols. Requiring symbol names to be unique allows us to support concurrent compilation for symbols using the (unique) symbol names as keys for tracking.

With these changes made, let's try our REPL again (I removed the dump of the anonymous functions this time, you should get the idea by now :) :

```
ready> def foo(x) x + 1;
            ready> foo(2);
            Evaluated to 3.000000
```

```
            ready> def foo(x) x + 2;
            ready> foo(2);
            Evaluated to 4.000000
```

It works!

Even with this simple code, we get some surprisingly powerful capabilities - check this out:

```
ready> extern sin(x);
            Read extern:
            declare double @sin(double)

            ready> extern cos(x);
            Read extern:
            declare double @cos(double)

            ready> sin(1.0);
            Read top-level expression:
            define double @2() {
            entry:
              ret double 0x3FEAED548F090CEE
            }

            Evaluated to 0.841471

            ready> def foo(x) sin(x)*sin(x) + cos(x)*cos(x);
            Read function definition:
            define double @foo(double %x) {
            entry:
              %calltmp = call double @sin(double %x)
              %multmp = fmul double %calltmp, %calltmp
              %calltmp2 = call double @cos(double %x)
              %multmp4 = fmul double %calltmp2, %calltmp2
              %addtmp = fadd double %multmp, %multmp4
              ret double %addtmp
            }

            ready> foo(4.0);
            Read top-level expression:
            define double @3() {
            entry:
              %calltmp = call double @foo(double 4.000000e+00)
              ret double %calltmp
            }

            Evaluated to 1.000000
```

Whoa, how does the JIT know about sin and cos? The answer is surprisingly simple: The KaleidoscopeJIT has a straightforward symbol resolution rule that it uses to find symbols that aren't available in any given module: First it searches all the modules that have already been added to the JIT, from the most recent to the oldest, to find the newest definition. If no definition is found inside the JIT, it falls back to calling "`dlsym("sin")`" on the Kaleidoscope process itself. Since "`sin`" is

defined within the JIT's address space, it simply patches up calls in the module to call the libm version of `sin` directly. But in some cases this even goes further: as sin and cos are names of standard math functions, the constant folder will directly evaluate the function calls to the correct result when called with constants like in the "`sin(1.0)`" above.

In the future we'll see how tweaking this symbol resolution rule can be used to enable all sorts of useful features, from security (restricting the set of symbols available to JIT'd code), to dynamic code generation based on symbol names, and even lazy compilation.

One immediate benefit of the symbol resolution rule is that we can now extend the language by writing arbitrary C++ code to implement operations. For example, if we add:

```
#ifdef _WIN32
            #define DLLEXPORT __declspec(dllexport)
            #else
            #define DLLEXPORT
            #endif

            /// putchard - putchar that takes a double and returns 0.
            extern "C" DLLEXPORT double putchard(double X) {
              fputc((char)X, stderr);
              return 0;
            }
```

Note, that for Windows we need to actually export the functions because the dynamic symbol loader will use `GetProcAddress` to find the symbols.

Now we can produce simple output to the console by using things like: "`extern putchard(x); putchard(120);`", which prints a lowercase 'x' on the console (120 is the ASCII code for 'x'). Similar code could be used to implement file I/O, console input, and many other capabilities in Kaleidoscope.

This completes the JIT and optimizer chapter of the Kaleidoscope tutorial. At this point, we can compile a non-Turing-complete programming language, optimize and JIT compile it in a user-driven way. Next up we'll look into extending the language with control flow constructs, tackling some interesting LLVM IR issues along the way.

4.5. Full Code Listing ¶

Here is the complete code listing for our running example, enhanced with the LLVM JIT and optimizer. To build this example, use:

```
# Compile
            clang++ -g toy.cpp `llvm-config --cxxflags --ldflags --system-libs --libs core orc
            # Run
            ./toy
```

If you are compiling this on Linux, make sure to add the "-rdynamic" option as well. This makes sure that the external functions are resolved properly at runtime.

Here is the code:

```
#include "../include/KaleidoscopeJIT.h"
            #include "llvm/ADT/APFloat.h"
            #include "llvm/ADT/STLExtras.h"
            #include "llvm/IR/BasicBlock.h"
            #include "llvm/IR/Constants.h"
            #include "llvm/IR/DerivedTypes.h"
            #include "llvm/IR/Function.h"
            #include "llvm/IR/IRBuilder.h"
            #include "llvm/IR/LLVMContext.h"
            #include "llvm/IR/Module.h"
            #include "llvm/IR/PassManager.h"
            #include "llvm/IR/Type.h"
            #include "llvm/IR/Verifier.h"
            #include "llvm/Passes/PassBuilder.h"
            #include "llvm/Passes/StandardInstrumentations.h"
            #include "llvm/Support/TargetSelect.h"
            #include "llvm/Target/TargetMachine.h"
            #include "llvm/Transforms/InstCombine/InstCombine.h"
            #include "llvm/Transforms/Scalar.h"
            #include "llvm/Transforms/Scalar/GVN.h"
            #include "llvm/Transforms/Scalar/Reassociate.h"

Next: Extending the language: control flow

5. Kaleidoscope: Extending the Language: Control Flow ¶

5.1. Chapter 5 Introduction ¶

Welcome to Chapter 5 of the "Implementing a language with LLVM" tutorial. Parts 1-4 described the implementation of the simple Kaleidoscope language and included support for generating LLVM IR, followed by optimizations and a JIT compiler. Unfortunately, as presented, Kaleidoscope is mostly useless: it has no control flow other than call and return. This means that you can't have conditional branches in the code, significantly limiting its power. In this episode of "build that compiler", we'll extend Kaleidoscope to have an if/then/else expression plus a simple 'for' loop.

5.2. If/Then/Else ¶

Extending Kaleidoscope to support if/then/else is quite straightforward. It basically requires adding support for this "new" concept to the lexer, parser, AST, and LLVM code emitter. This example is nice, because it shows how easy it is to "grow" a language over time, incrementally extending it as new ideas are discovered.

Before we get going on "how" we add this extension, let's talk about "what" we want. The basic idea is that we want to be able to write this sort of thing:

```
def fib(x)
             if x < 3 then
```

```
    1
  else
    fib(x-1)+fib(x-2);
```

In Kaleidoscope, every construct is an expression: there are no statements. As such, the if/then/else expression needs to return a value like any other. Since we're using a mostly functional form, we'll have it evaluate its conditional, then return the 'then' or 'else' value based on how the condition was resolved. This is very similar to the C "?:" expression.

The semantics of the if/then/else expression is that it evaluates the condition to a boolean equality value: 0.0 is considered to be false and everything else is considered to be true. If the condition is true, the first subexpression is evaluated and returned, if the condition is false, the second subexpression is evaluated and returned. Since Kaleidoscope allows side-effects, this behavior is important to nail down.

Now that we know what we "want", let's break this down into its constituent pieces.

5.2.1. Lexer Extensions for If/Then/Else ¶

The lexer extensions are straightforward. First we add new enum values for the relevant tokens:

```
// control
            tok_if = -6,
            tok_then = -7,
            tok_else = -8,
```

Once we have that, we recognize the new keywords in the lexer. This is pretty simple stuff:

```
...
            if (IdentifierStr == "def")
              return tok_def;
            if (IdentifierStr == "extern")
              return tok_extern;
            if (IdentifierStr == "if")
              return tok_if;
            if (IdentifierStr == "then")
              return tok_then;
            if (IdentifierStr == "else")
              return tok_else;
            return tok_identifier;
```

5.2.2. AST Extensions for If/Then/Else ¶

To represent the new expression we add a new AST node for it:

```
/// IfExprAST - Expression class for if/then/else.
            class IfExprAST : public ExprAST {
              std::unique_ptr<ExprAST> Cond, Then, Else;
```

```
public:
  IfExprAST(std::unique_ptr<ExprAST> Cond, std::unique_ptr<ExprAST> Then,
            std::unique_ptr<ExprAST> Else)
    : Cond(std::move(Cond)), Then(std::move(Then)), Else(std::move(Else)) {}

  Value *codegen() override;
};
```

The AST node just has pointers to the various subexpressions.

5.2.3. Parser Extensions for If/Then/Else ¶

Now that we have the relevant tokens coming from the lexer and we have the AST node to build, our parsing logic is relatively straightforward. First we define a new parsing function:

```
/// ifexpr ::= 'if' expression 'then' expression 'else' expression
static std::unique_ptr<ExprAST> ParseIfExpr() {
  getNextToken();  // eat the if.

  // condition.
  auto Cond = ParseExpression();
  if (!Cond)
    return nullptr;

  if (CurTok != tok_then)
    return LogError("expected then");
  getNextToken();  // eat the then

  auto Then = ParseExpression();
  if (!Then)
    return nullptr;

  if (CurTok != tok_else)
    return LogError("expected else");

  getNextToken();

  auto Else = ParseExpression();
  if (!Else)
    return nullptr;

  return std::make_unique<IfExprAST>(std::move(Cond), std::move(Then),
                                     std::move(Else));
}
```

Next we hook it up as a primary expression:

```
static std::unique_ptr<ExprAST> ParsePrimary() {
  switch (CurTok) {
  default:
    return LogError("unknown token when expecting an expression");
  case tok_identifier:
    return ParseIdentifierExpr();
```

```
      case tok_number:
        return ParseNumberExpr();
      case '(':
        return ParseParenExpr();
      case tok_if:
        return ParseIfExpr();
      }
    }
```

5.2.4. LLVM IR for If/Then/Else ¶

Now that we have it parsing and building the AST, the final piece is adding LLVM code generation support. This is the most interesting part of the if/then/else example, because this is where it starts to introduce new concepts. All of the code above has been thoroughly described in previous chapters.

To motivate the code we want to produce, let's take a look at a simple example. Consider:

```
extern foo();
            extern bar();
            def baz(x) if x then foo() else bar();
```

If you disable optimizations, the code you'll (soon) get from Kaleidoscope looks like this:

```
declare double @foo()

            declare double @bar()

            define double @baz(double %x) {
            entry:
              %ifcond = fcmp one double %x, 0.000000e+00
              br i1 %ifcond, label %then, label %else

            then:       ; preds = %entry
              %calltmp = call double @foo()
              br label %ifcont

            else:       ; preds = %entry
              %calltmp1 = call double @bar()
              br label %ifcont

            ifcont:     ; preds = %else, %then
              %iftmp = phi double [ %calltmp, %then ], [ %calltmp1, %else ]
              ret double %iftmp
            }
```

To visualize the control flow graph, you can use a nifty feature of the LLVM 'opt' tool. If you put this LLVM IR into "t.ll" and run "`llvm-as < t.ll | opt -passes=view-cfg`", a window will pop up and you'll see this graph:

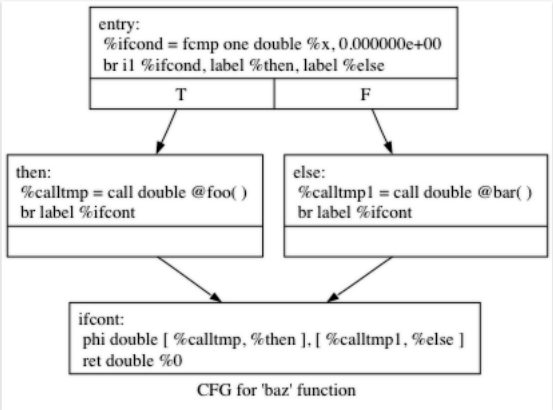

Fig. 5.1 Example CFG ¶

Another way to get this is to call "`F->viewCFG()`" or "`F->viewCFGOnly()`" (where `F` is a "`Function*`") either by inserting actual calls into the code and recompiling or by calling these in the debugger. LLVM has many nice features for visualizing various graphs.

Getting back to the generated code, it is fairly simple: the entry block evaluates the conditional expression ("x" in our case here) and compares the result to 0.0 with the "`fcmp one`" instruction ('one' is "Ordered and Not Equal"). Based on the result of this expression, the code jumps to either the "then" or "else" blocks, which contain the expressions for the true/false cases.

Once the then/else blocks are finished executing, they both branch back to the 'ifcont' block to execute the code that happens after the if/then/else. In this case the only thing left to do is to return to the caller of the function. The question then becomes: how does the code know which expression to return?

The answer to this question involves an important SSA operation: the Phi operation. If you're not familiar with SSA, the wikipedia article is a good introduction and there are various other introductions to it available on your favorite search engine. The short version is that "execution" of the Phi operation requires "remembering" which block control came from. The Phi operation takes on the value corresponding to the input control block. In this case, if control comes in from the "then" block, it gets the value of "calltmp". If control comes from the "else" block, it gets the value of "calltmp1".

At this point, you are probably starting to think "Oh no! This means my simple and elegant front-end will have to start generating SSA form in order to use LLVM!". Fortunately, this is not the case, and we strongly advise *not* implementing an SSA construction algorithm in your front-end unless there is an amazingly good reason to do so. In practice, there are two sorts of values that float around in code written for your average imperative programming language that might need Phi nodes:

1. Code that involves user variables: `x = 1; x = x + 1;`
2. Values that are implicit in the structure of your AST, such as the Phi node in this case.

In Chapter 7 of this tutorial ("mutable variables"), we'll talk about #1 in depth. For now, just believe me that you don't need SSA construction to handle this case. For #2, you have the choice of using

the techniques that we will describe for #1, or you can insert Phi nodes directly, if convenient. In this case, it is really easy to generate the Phi node, so we choose to do it directly.

Okay, enough of the motivation and overview, let's generate code!

5.2.5. Code Generation for If/Then/Else ¶

In order to generate code for this, we implement the codegen method for IfExprAST:

```
Value *IfExprAST::codegen() {
              Value *CondV = Cond->codegen();
              if (!CondV)
                return nullptr;

              // Convert condition to a bool by comparing non-equal to 0.0.
              CondV = Builder->CreateFCmpONE(
                  CondV, ConstantFP::get(*TheContext, APFloat(0.0)), "ifcond");
```

This code is straightforward and similar to what we saw before. We emit the expression for the condition, then compare that value to zero to get a truth value as a 1-bit (bool) value.

```
Function *TheFunction = Builder->GetInsertBlock()->getParent();

            // Create blocks for the then and else cases.  Insert the 'then' block at the
            // end of the function.
            BasicBlock *ThenBB =
                BasicBlock::Create(*TheContext, "then", TheFunction);
            BasicBlock *ElseBB = BasicBlock::Create(*TheContext, "else");
            BasicBlock *MergeBB = BasicBlock::Create(*TheContext, "ifcont");

            Builder->CreateCondBr(CondV, ThenBB, ElseBB);
```

This code creates the basic blocks that are related to the if/then/else statement, and correspond directly to the blocks in the example above. The first line gets the current Function object that is being built. It gets this by asking the builder for the current BasicBlock, and asking that block for its "parent" (the function it is currently embedded into).

Once it has that, it creates three blocks. Note that it passes "TheFunction" into the constructor for the "then" block. This causes the constructor to automatically insert the new block into the end of the specified function. The other two blocks are created, but aren't yet inserted into the function.

Once the blocks are created, we can emit the conditional branch that chooses between them. Note that creating new blocks does not implicitly affect the IRBuilder, so it is still inserting into the block that the condition went into. Also note that it is creating a branch to the "then" block and the "else" block, even though the "else" block isn't inserted into the function yet. This is all ok: it is the standard way that LLVM supports forward references.

```
// Emit then value.
            Builder->SetInsertPoint(ThenBB);
```

```
            Value *ThenV = Then->codegen();
            if (!ThenV)
              return nullptr;

            Builder->CreateBr(MergeBB);
            // Codegen of 'Then' can change the current block, update ThenBB for the PHI.
            ThenBB = Builder->GetInsertBlock();
```

After the conditional branch is inserted, we move the builder to start inserting into the "then" block. Strictly speaking, this call moves the insertion point to be at the end of the specified block. However, since the "then" block is empty, it also starts out by inserting at the beginning of the block. :)

Once the insertion point is set, we recursively codegen the "then" expression from the AST. To finish off the "then" block, we create an unconditional branch to the merge block. One interesting (and very important) aspect of the LLVM IR is that it requires all basic blocks to be "terminated" with a control flow instruction such as return or branch. This means that all control flow, *including fall throughs* must be made explicit in the LLVM IR. If you violate this rule, the verifier will emit an error.

The final line here is quite subtle, but is very important. The basic issue is that when we create the Phi node in the merge block, we need to set up the block/value pairs that indicate how the Phi will work. Importantly, the Phi node expects to have an entry for each predecessor of the block in the CFG. Why then, are we getting the current block when we just set it to ThenBB 5 lines above? The problem is that the "Then" expression may actually itself change the block that the Builder is emitting into if, for example, it contains a nested "if/then/else" expression. Because calling `codegen()` recursively could arbitrarily change the notion of the current block, we are required to get an up-to-date value for code that will set up the Phi node.

```
// Emit else block.
            TheFunction->insert(TheFunction->end(), ElseBB);
            Builder->SetInsertPoint(ElseBB);

            Value *ElseV = Else->codegen();
            if (!ElseV)
              return nullptr;

            Builder->CreateBr(MergeBB);
            // codegen of 'Else' can change the current block, update ElseBB for the PHI.
            ElseBB = Builder->GetInsertBlock();
```

Code generation for the 'else' block is basically identical to codegen for the 'then' block. The only significant difference is the first line, which adds the 'else' block to the function. Recall previously that the 'else' block was created, but not added to the function. Now that the 'then' and 'else' blocks are emitted, we can finish up with the merge code:

```
  // Emit merge block.
              TheFunction->insert(TheFunction->end(), MergeBB);
              Builder->SetInsertPoint(MergeBB);
              PHINode *PN =
                Builder->CreatePHI(Type::getDoubleTy(*TheContext), 2, "iftmp");

              PN->addIncoming(ThenV, ThenBB);
              PN->addIncoming(ElseV, ElseBB);
              return PN;
            }
```

The first two lines here are now familiar: the first adds the “merge” block to the Function object (it was previously floating, like the else block above). The second changes the insertion point so that newly created code will go into the “merge” block. Once that is done, we need to create the PHI node and set up the block/value pairs for the PHI.

Finally, the CodeGen function returns the phi node as the value computed by the if/then/else expression. In our example above, this returned value will feed into the code for the top-level function, which will create the return instruction.

Overall, we now have the ability to execute conditional code in Kaleidoscope. With this extension, Kaleidoscope is a fairly complete language that can calculate a wide variety of numeric functions. Next up we’ll add another useful expression that is familiar from non-functional languages…

5.3. ‘for’ Loop Expression ¶

Now that we know how to add basic control flow constructs to the language, we have the tools to add more powerful things. Let’s add something more aggressive, a ‘for’ expression:

```
extern putchard(char);
            def printstar(n)
              for i = 1, i < n, 1.0 in
                putchard(42);  # ascii 42 = '*'

            # print 100 '*' characters
            printstar(100);
```

This expression defines a new variable (“i” in this case) which iterates from a starting value, while the condition (“i < n” in this case) is true, incrementing by an optional step value (“1.0” in this case). If the step value is omitted, it defaults to 1.0. While the loop is true, it executes its body expression. Because we don’t have anything better to return, we’ll just define the loop as always returning 0.0. In the future when we have mutable variables, it will get more useful.

As before, let’s talk about the changes that we need to Kaleidoscope to support this.

5.3.1. Lexer Extensions for the ‘for’ Loop ¶

The lexer extensions are the same sort of thing as for if/then/else:

```
... in enum Token ...
            // control
            tok_if = -6, tok_then = -7, tok_else = -8,
            tok_for = -9, tok_in = -10

            ... in gettok ...
            if (IdentifierStr == "def")
              return tok_def;
            if (IdentifierStr == "extern")
              return tok_extern;
            if (IdentifierStr == "if")
              return tok_if;
            if (IdentifierStr == "then")
              return tok_then;
            if (IdentifierStr == "else")
              return tok_else;
            if (IdentifierStr == "for")
              return tok_for;
            if (IdentifierStr == "in")
              return tok_in;
            return tok_identifier;
```

5.3.2. AST Extensions for the ‘for’ Loop ¶

The AST node is just as simple. It basically boils down to capturing the variable name and the constituent expressions in the node.

```
/// ForExprAST - Expression class for for/in.
            class ForExprAST : public ExprAST {
              std::string VarName;
              std::unique_ptr<ExprAST> Start, End, Step, Body;

            public:
              ForExprAST(const std::string &VarName, std::unique_ptr<ExprAST> Start,
                         std::unique_ptr<ExprAST> End, std::unique_ptr<ExprAST> Step,
                         std::unique_ptr<ExprAST> Body)
                : VarName(VarName), Start(std::move(Start)), End(std::move(End)),
                  Step(std::move(Step)), Body(std::move(Body)) {}

              Value *codegen() override;
            };
```

5.3.3. Parser Extensions for the ‘for’ Loop ¶

The parser code is also fairly standard. The only interesting thing here is handling of the optional step value. The parser code handles it by checking to see if the second comma is present. If not, it sets the step value to null in the AST node:

```
/// forexpr ::= 'for' identifier '=' expr ',' expr (',' expr)? 'in' expression
            static std::unique_ptr<ExprAST> ParseForExpr() {
              getNextToken();  // eat the for.
```

```
    if (CurTok != tok_identifier)
      return LogError("expected identifier after for");

    std::string IdName = IdentifierStr;
    getNextToken();  // eat identifier.

    if (CurTok != '=')
      return LogError("expected '=' after for");
    getNextToken();  // eat '='.

    auto Start = ParseExpression();
    if (!Start)
      return nullptr;
    if (CurTok != ',')
      return LogError("expected ',' after for start value");
    getNextToken();

    auto End = ParseExpression();
    if (!End)
      return nullptr;

    // The step value is optional.
    std::unique_ptr<ExprAST> Step;
    if (CurTok == ',') {
      getNextToken();
      Step = ParseExpression();
      if (!Step)
        return nullptr;
    }

    if (CurTok != tok_in)
      return LogError("expected 'in' after for");
    getNextToken();  // eat 'in'.

    auto Body = ParseExpression();
    if (!Body)
      return nullptr;

    return std::make_unique<ForExprAST>(IdName, std::move(Start),
                                        std::move(End), std::move(Step),
                                        std::move(Body));
  }
```

And again we hook it up as a primary expression:

```
static std::unique_ptr<ExprAST> ParsePrimary() {
    switch (CurTok) {
    default:
      return LogError("unknown token when expecting an expression");
    case tok_identifier:
      return ParseIdentifierExpr();
    case tok_number:
      return ParseNumberExpr();
    case '(':
      return ParseParenExpr();
```

```
    case tok_if:
      return ParseIfExpr();
    case tok_for:
      return ParseForExpr();
    }
  }
```

5.3.4. LLVM IR for the ‘for’ Loop ¶

Now we get to the good part: the LLVM IR we want to generate for this thing. With the simple example above, we get this LLVM IR (note that this dump is generated with optimizations disabled for clarity):

```
declare double @putchard(double)

  define double @printstar(double %n) {
  entry:
    ; initial value = 1.0 (inlined into phi)
    br label %loop

  loop:       ; preds = %loop, %entry
    %i = phi double [ 1.000000e+00, %entry ], [ %nextvar, %loop ]
    ; body
    %calltmp = call double @putchard(double 4.200000e+01)
    ; increment
    %nextvar = fadd double %i, 1.000000e+00

    ; termination test
    %cmptmp = fcmp ult double %i, %n
    %booltmp = uitofp i1 %cmptmp to double
    %loopcond = fcmp one double %booltmp, 0.000000e+00
    br i1 %loopcond, label %loop, label %afterloop

  afterloop:      ; preds = %loop
    ; loop always returns 0.0
    ret double 0.000000e+00
  }
```

This loop contains all the same constructs we saw before: a phi node, several expressions, and some basic blocks. Let’s see how this fits together.

5.3.5. Code Generation for the ‘for’ Loop ¶

The first part of codegen is very simple: we just output the start expression for the loop value:

```
Value *ForExprAST::codegen() {
  // Emit the start code first, without 'variable' in scope.
  Value *StartVal = Start->codegen();
  if (!StartVal)
    return nullptr;
```

With this out of the way, the next step is to set up the LLVM basic block for the start of the loop body. In the case above, the whole loop body is one block, but remember that the body code itself could consist of multiple blocks (e.g. if it contains an if/then/else or a for/in expression).

```
// Make the new basic block for the loop header, inserting after current
            // block.
            Function *TheFunction = Builder->GetInsertBlock()->getParent();
            BasicBlock *PreheaderBB = Builder->GetInsertBlock();
            BasicBlock *LoopBB =
                BasicBlock::Create(*TheContext, "loop", TheFunction);

            // Insert an explicit fall through from the current block to the LoopBB.
            Builder->CreateBr(LoopBB);
```

This code is similar to what we saw for if/then/else. Because we will need it to create the Phi node, we remember the block that falls through into the loop. Once we have that, we create the actual block that starts the loop and create an unconditional branch for the fall-through between the two blocks.

```
// Start insertion in LoopBB.
            Builder->SetInsertPoint(LoopBB);

            // Start the PHI node with an entry for Start.
            PHINode *Variable = Builder->CreatePHI(Type::getDoubleTy(*TheContext),
                                                   2, VarName);
            Variable->addIncoming(StartVal, PreheaderBB);
```

Now that the “preheader” for the loop is set up, we switch to emitting code for the loop body. To begin with, we move the insertion point and create the PHI node for the loop induction variable. Since we already know the incoming value for the starting value, we add it to the Phi node. Note that the Phi will eventually get a second value for the backedge, but we can’t set it up yet (because it doesn’t exist!).

```
// Within the loop, the variable is defined equal to the PHI node.  If it
            // shadows an existing variable, we have to restore it, so save it now.
            Value *OldVal = NamedValues[VarName];
            NamedValues[VarName] = Variable;

            // Emit the body of the loop.  This, like any other expr, can change the
            // current BB.  Note that we ignore the value computed by the body, but don't
            // allow an error.
            if (!Body->codegen())
              return nullptr;
```

Now the code starts to get more interesting. Our ‘for’ loop introduces a new variable to the symbol table. This means that our symbol table can now contain either function arguments or loop variables. To handle this, before we codegen the body of the loop, we add the loop variable as the current value for its name. Note that it is possible that there is a variable of the same name in the

outer scope. It would be easy to make this an error (emit an error and return null if there is already an entry for VarName) but we choose to allow shadowing of variables. In order to handle this correctly, we remember the Value that we are potentially shadowing in `OldVal` (which will be null if there is no shadowed variable).

Once the loop variable is set into the symbol table, the code recursively codegen's the body. This allows the body to use the loop variable: any references to it will naturally find it in the symbol table.

```
// Emit the step value.
            Value *StepVal = nullptr;
            if (Step) {
              StepVal = Step->codegen();
              if (!StepVal)
                return nullptr;
            } else {
              // If not specified, use 1.0.
              StepVal = ConstantFP::get(*TheContext, APFloat(1.0));
            }

            Value *NextVar = Builder->CreateFAdd(Variable, StepVal, "nextvar");
```

Now that the body is emitted, we compute the next value of the iteration variable by adding the step value, or 1.0 if it isn't present. '`NextVar`' will be the value of the loop variable on the next iteration of the loop.

```
// Compute the end condition.
            Value *EndCond = End->codegen();
            if (!EndCond)
              return nullptr;

            // Convert condition to a bool by comparing non-equal to 0.0.
            EndCond = Builder->CreateFCmpONE(
                EndCond, ConstantFP::get(*TheContext, APFloat(0.0)), "loopcond");
```

Finally, we evaluate the exit value of the loop, to determine whether the loop should exit. This mirrors the condition evaluation for the if/then/else statement.

```
// Create the "after loop" block and insert it.
            BasicBlock *LoopEndBB = Builder->GetInsertBlock();
            BasicBlock *AfterBB =
                BasicBlock::Create(*TheContext, "afterloop", TheFunction);

            // Insert the conditional branch into the end of LoopEndBB.
            Builder->CreateCondBr(EndCond, LoopBB, AfterBB);

            // Any new code will be inserted in AfterBB.
            Builder->SetInsertPoint(AfterBB);
```

With the code for the body of the loop complete, we just need to finish up the control flow for it. This code remembers the end block (for the phi node), then creates the block for the loop exit ("afterloop"). Based on the value of the exit condition, it creates a conditional branch that chooses between executing the loop again and exiting the loop. Any future code is emitted in the "afterloop" block, so it sets the insertion position to it.

```
  // Add a new entry to the PHI node for the backedge.
              Variable->addIncoming(NextVar, LoopEndBB);

              // Restore the unshadowed variable.
              if (OldVal)
                NamedValues[VarName] = OldVal;
              else
                NamedValues.erase(VarName);

              // for expr always returns 0.0.
              return Constant::getNullValue(Type::getDoubleTy(*TheContext));
            }
```

The final code handles various cleanups: now that we have the "NextVar" value, we can add the incoming value to the loop PHI node. After that, we remove the loop variable from the symbol table, so that it isn't in scope after the for loop. Finally, code generation of the for loop always returns 0.0, so that is what we return from `ForExprAST::codegen()`.

With this, we conclude the "adding control flow to Kaleidoscope" chapter of the tutorial. In this chapter we added two control flow constructs, and used them to motivate a couple of aspects of the LLVM IR that are important for front-end implementors to know. In the next chapter of our saga, we will get a bit crazier and add user-defined operators to our poor innocent language.

5.4. Full Code Listing ¶

Here is the complete code listing for our running example, enhanced with the if/then/else and for expressions. To build this example, use:

```
# Compile
            clang++ -g toy.cpp `llvm-config --cxxflags --ldflags --system-libs --libs core orc
            # Run
            ./toy
```

Here is the code:

```
#include "../include/KaleidoscopeJIT.h"
            #include "llvm/ADT/APFloat.h"
            #include "llvm/ADT/STLExtras.h"
            #include "llvm/IR/BasicBlock.h"
            #include "llvm/IR/Constants.h"
            #include "llvm/IR/DerivedTypes.h"
            #include "llvm/IR/Function.h"
            #include "llvm/IR/IRBuilder.h"
```

```cpp
#include "llvm/IR/Instructions.h"
#include "llvm/IR/LLVMContext.h"
#include "llvm/IR/Module.h"
#include "llvm/IR/PassManager.h"
#include "llvm/IR/Type.h"
#include "llvm/IR/Verifier.h"
#include "llvm/Passes/PassBuilder.h"
#include "llvm/Passes/StandardInstrumentations.h"
#include "llvm/Support/TargetSelect.h"
#include "llvm/Target/TargetMachine.h"

Next: Extending the language: user-defined operators

6. Kaleidoscope: Extending the Language: User-defined Operators ¶

6.1. Chapter 6 Introduction ¶

Welcome to Chapter 6 of the “Implementing a language with LLVM” tutorial. At this point in our tutorial, we now have a fully functional language that is fairly minimal, but also useful. There is still one big problem with it, however. Our language doesn’t have many useful operators (like division, logical negation, or even any comparisons besides less-than).

This chapter of the tutorial takes a wild digression into adding user-defined operators to the simple and beautiful Kaleidoscope language. This digression now gives us a simple and ugly language in some ways, but also a powerful one at the same time. One of the great things about creating your own language is that you get to decide what is good or bad. In this tutorial we'll assume that it is okay to use this as a way to show some interesting parsing techniques.

At the end of this tutorial, we'll run through an example Kaleidoscope application that renders the Mandelbrot set. This gives an example of what you can build with Kaleidoscope and its feature set.

6.2. User-defined Operators: the Idea ¶

The "operator overloading" that we will add to Kaleidoscope is more general than in languages like C++. In C++, you are only allowed to redefine existing operators: you can't programmatically change the grammar, introduce new operators, change precedence levels, etc. In this chapter, we will add this capability to Kaleidoscope, which will let the user round out the set of operators that are supported.

The point of going into user-defined operators in a tutorial like this is to show the power and flexibility of using a hand-written parser. Thus far, the parser we have been implementing uses recursive descent for most parts of the grammar and operator precedence parsing for the expressions. See Chapter 2 for details. By using operator precedence parsing, it is very easy to allow the programmer to introduce new operators into the grammar: the grammar is dynamically extensible as the JIT runs.

The two specific features we'll add are programmable unary operators (right now, Kaleidoscope has no unary operators at all) as well as binary operators. An example of this is:

```
# Logical unary not.
            def unary!(v)
              if v then
                0
              else
                1;

            # Define > with the same precedence as <.
            def binary> 10 (LHS RHS)
              RHS < LHS;

            # Binary "logical or", (note that it does not "short circuit")
            def binary| 5 (LHS RHS)
              if LHS then
                1
              else if RHS then
                1
              else
                0;

            # Define = with slightly lower precedence than relationals.
            def binary= 9 (LHS RHS)
              !(LHS < RHS | LHS > RHS);
```

Many languages aspire to being able to implement their standard runtime library in the language itself. In Kaleidoscope, we can implement significant parts of the language in the library!

We will break down implementation of these features into two parts: implementing support for user-defined binary operators and adding unary operators.

6.3. User-defined Binary Operators ¶

Adding support for user-defined binary operators is pretty simple with our current framework. We'll first add support for the unary/binary keywords:

```
enum Token {
              ...
              // operators
              tok_binary = -11,
              tok_unary = -12
            };
            ...
            static int gettok() {
            ...
                if (IdentifierStr == "for")
                  return tok_for;
                if (IdentifierStr == "in")
                  return tok_in;
                if (IdentifierStr == "binary")
                  return tok_binary;
                if (IdentifierStr == "unary")
                  return tok_unary;
                return tok_identifier;
```

This just adds lexer support for the unary and binary keywords, like we did in previous chapters. One nice thing about our current AST, is that we represent binary operators with full generalisation by using their ASCII code as the opcode. For our extended operators, we'll use this same representation, so we don't need any new AST or parser support.

On the other hand, we have to be able to represent the definitions of these new operators, in the "def binary| 5" part of the function definition. In our grammar so far, the "name" for the function definition is parsed as the "prototype" production and into the PrototypeAST AST node. To represent our new user-defined operators as prototypes, we have to extend the PrototypeAST AST node like this:

```
/// PrototypeAST - This class represents the "prototype" for a function,
            /// which captures its argument names as well as if it is an operator.
            class PrototypeAST {
              std::string Name;
              std::vector<std::string> Args;
              bool IsOperator;
              unsigned Precedence;  // Precedence if a binary op.

            public:
              PrototypeAST(const std::string &Name, std::vector<std::string> Args,
```

```
                    bool IsOperator = false, unsigned Prec = 0)
      : Name(Name), Args(std::move(Args)), IsOperator(IsOperator),
        Precedence(Prec) {}

    Function *codegen();
    const std::string &getName() const { return Name; }

    bool isUnaryOp() const { return IsOperator && Args.size() == 1; }
    bool isBinaryOp() const { return IsOperator && Args.size() == 2; }

    char getOperatorName() const {
      assert(isUnaryOp() || isBinaryOp());
      return Name[Name.size() - 1];
    }

    unsigned getBinaryPrecedence() const { return Precedence; }
  };
```

Basically, in addition to knowing a name for the prototype, we now keep track of whether it was an operator, and if it was, what precedence level the operator is at. The precedence is only used for binary operators (as you'll see below, it just doesn't apply for unary operators). Now that we have a way to represent the prototype for a user-defined operator, we need to parse it:

```
/// prototype
  ///   ::= id '(' id* ')'
  ///   ::= binary LETTER number? (id, id)
  static std::unique_ptr<PrototypeAST> ParsePrototype() {
    std::string FnName;

    unsigned Kind = 0;  // 0 = identifier, 1 = unary, 2 = binary.
    unsigned BinaryPrecedence = 30;

    switch (CurTok) {
    default:
      return LogErrorP("Expected function name in prototype");
    case tok_identifier:
      FnName = IdentifierStr;
      Kind = 0;
      getNextToken();
      break;
    case tok_binary:
      getNextToken();
      if (!isascii(CurTok))
        return LogErrorP("Expected binary operator");
      FnName = "binary";
      FnName += (char)CurTok;
      Kind = 2;
      getNextToken();

      // Read the precedence if present.
      if (CurTok == tok_number) {
        if (NumVal < 1 || NumVal > 100)
          return LogErrorP("Invalid precedence: must be 1..100");
        BinaryPrecedence = (unsigned)NumVal;
        getNextToken();
```

```
    }
    break;
  }

  if (CurTok != '(')
    return LogErrorP("Expected '(' in prototype");

  std::vector<std::string> ArgNames;
  while (getNextToken() == tok_identifier)
    ArgNames.push_back(IdentifierStr);
  if (CurTok != ')')
    return LogErrorP("Expected ')' in prototype");

  // success.
  getNextToken();  // eat ')'.

  // Verify right number of names for operator.
  if (Kind && ArgNames.size() != Kind)
    return LogErrorP("Invalid number of operands for operator");

  return std::make_unique<PrototypeAST>(FnName, std::move(ArgNames), Kind != 0,
                                        BinaryPrecedence);
}
```

This is all fairly straightforward parsing code, and we have already seen a lot of similar code in the past. One interesting part about the code above is the couple lines that set up FnName for binary operators. This builds names like “binary@” for a newly defined “@” operator. It then takes advantage of the fact that symbol names in the LLVM symbol table are allowed to have any character in them, including embedded nul characters.

The next interesting thing to add, is codegen support for these binary operators. Given our current structure, this is a simple addition of a default case for our existing binary operator node:

```
Value *BinaryExprAST::codegen() {
  Value *L = LHS->codegen();
  Value *R = RHS->codegen();
  if (!L || !R)
    return nullptr;

  switch (Op) {
  case '+':
    return Builder->CreateFAdd(L, R, "addtmp");
  case '-':
    return Builder->CreateFSub(L, R, "subtmp");
  case '*':
    return Builder->CreateFMul(L, R, "multtmp");
  case '<':
    L = Builder->CreateFCmpULT(L, R, "cmptmp");
    // Convert bool 0/1 to double 0.0 or 1.0
    return Builder->CreateUIToFP(L, Type::getDoubleTy(*TheContext),
                                 "booltmp");
  default:
    break;
  }
```

```
      // If it wasn't a builtin binary operator, it must be a user defined one. Emit
      // a call to it.
      Function *F = getFunction(std::string("binary") + Op);
      assert(F && "binary operator not found!");

      Value *Ops[2] = { L, R };
      return Builder->CreateCall(F, Ops, "binop");
    }
```

As you can see above, the new code is actually really simple. It just does a lookup for the appropriate operator in the symbol table and generates a function call to it. Since user-defined operators are just built as normal functions (because the "prototype" boils down to a function with the right name) everything falls into place.

The final piece of code we are missing, is a bit of top-level magic:

```
Function *FunctionAST::codegen() {
      // Transfer ownership of the prototype to the FunctionProtos map, but keep a
      // reference to it for use below.
      auto &P = *Proto;
      FunctionProtos[Proto->getName()] = std::move(Proto);
      Function *TheFunction = getFunction(P.getName());
      if (!TheFunction)
        return nullptr;

      // If this is an operator, install it.
      if (P.isBinaryOp())
        BinopPrecedence[P.getOperatorName()] = P.getBinaryPrecedence();

      // Create a new basic block to start insertion into.
      BasicBlock *BB = BasicBlock::Create(*TheContext, "entry", TheFunction);
      ...
```

Basically, before codegening a function, if it is a user-defined operator, we register it in the precedence table. This allows the binary operator parsing logic we already have in place to handle it. Since we are working on a fully-general operator precedence parser, this is all we need to do to "extend the grammar".

Now we have useful user-defined binary operators. This builds a lot on the previous framework we built for other operators. Adding unary operators is a bit more challenging, because we don't have any framework for it yet - let's see what it takes.

6.4. User-defined Unary Operators ¶

Since we don't currently support unary operators in the Kaleidoscope language, we'll need to add everything to support them. Above, we added simple support for the 'unary' keyword to the lexer. In addition to that, we need an AST node:

```
/// UnaryExprAST - Expression class for a unary operator.
class UnaryExprAST : public ExprAST {
  char Opcode;
  std::unique_ptr<ExprAST> Operand;

public:
  UnaryExprAST(char Opcode, std::unique_ptr<ExprAST> Operand)
    : Opcode(Opcode), Operand(std::move(Operand)) {}

  Value *codegen() override;
};
```

This AST node is very simple and obvious by now. It directly mirrors the binary operator AST node, except that it only has one child. With this, we need to add the parsing logic. Parsing a unary operator is pretty simple: we'll add a new function to do it:

```
/// unary
///   ::= primary
///   ::= '!' unary
static std::unique_ptr<ExprAST> ParseUnary() {
  // If the current token is not an operator, it must be a primary expr.
  if (!isascii(CurTok) || CurTok == '(' || CurTok == ',')
    return ParsePrimary();

  // If this is a unary operator, read it.
  int Opc = CurTok;
  getNextToken();
  if (auto Operand = ParseUnary())
    return std::make_unique<UnaryExprAST>(Opc, std::move(Operand));
  return nullptr;
}
```

The grammar we add is pretty straightforward here. If we see a unary operator when parsing a primary operator, we eat the operator as a prefix and parse the remaining piece as another unary operator. This allows us to handle multiple unary operators (e.g. "!!x"). Note that unary operators can't have ambiguous parses like binary operators can, so there is no need for precedence information.

The problem with this function, is that we need to call ParseUnary from somewhere. To do this, we change previous callers of ParsePrimary to call ParseUnary instead:

```
/// binoprhs
///   ::= ('+' unary)*
static std::unique_ptr<ExprAST> ParseBinOpRHS(int ExprPrec,
                                              std::unique_ptr<ExprAST> LHS) {
  ...
    // Parse the unary expression after the binary operator.
    auto RHS = ParseUnary();
    if (!RHS)
      return nullptr;
  ...
```

```
}
/// expression
///   ::= unary binoprhs
///
static std::unique_ptr<ExprAST> ParseExpression() {
  auto LHS = ParseUnary();
  if (!LHS)
    return nullptr;

  return ParseBinOpRHS(0, std::move(LHS));
}
```

With these two simple changes, we are now able to parse unary operators and build the AST for them. Next up, we need to add parser support for prototypes, to parse the unary operator prototype. We extend the binary operator code above with:

```
/// prototype
///   ::= id '(' id* ')'
///   ::= binary LETTER number? (id, id)
///   ::= unary LETTER (id)
static std::unique_ptr<PrototypeAST> ParsePrototype() {
  std::string FnName;

  unsigned Kind = 0;  // 0 = identifier, 1 = unary, 2 = binary.
  unsigned BinaryPrecedence = 30;

  switch (CurTok) {
  default:
    return LogErrorP("Expected function name in prototype");
  case tok_identifier:
    FnName = IdentifierStr;
    Kind = 0;
    getNextToken();
    break;
  case tok_unary:
    getNextToken();
    if (!isascii(CurTok))
      return LogErrorP("Expected unary operator");
    FnName = "unary";
    FnName += (char)CurTok;
    Kind = 1;
    getNextToken();
    break;
  case tok_binary:
    ...
```

As with binary operators, we name unary operators with a name that includes the operator character. This assists us at code generation time. Speaking of, the final piece we need to add is codegen support for unary operators. It looks like this:

```
Value *UnaryExprAST::codegen() {
  Value *OperandV = Operand->codegen();
```

```
  if (!OperandV)
    return nullptr;

  Function *F = getFunction(std::string("unary") + Opcode);
  if (!F)
    return LogErrorV("Unknown unary operator");

  return Builder->CreateCall(F, OperandV, "unop");
}
```

This code is similar to, but simpler than, the code for binary operators. It is simpler primarily because it doesn't need to handle any predefined operators.

6.5. Kicking the Tires ¶

It is somewhat hard to believe, but with a few simple extensions we've covered in the last chapters, we have grown a real-ish language. With this, we can do a lot of interesting things, including I/O, math, and a bunch of other things. For example, we can now add a nice sequencing operator (printd is defined to print out the specified value and a newline):

```
ready> extern printd(x);
            Read extern:
            declare double @printd(double)

            ready> def binary : 1 (x y) 0;  # Low-precedence operator that ignores operands.
            ...
            ready> printd(123) : printd(456) : printd(789);
            123.000000
            456.000000
            789.000000
            Evaluated to 0.000000
```

We can also define a bunch of other "primitive" operations, such as:

```
# Logical unary not.
            def unary!(v)
              if v then
                0
              else
                1;

            # Unary negate.
            def unary-(v)
              0-v;

            # Define > with the same precedence as <.
            def binary> 10 (LHS RHS)
              RHS < LHS;

            # Binary logical or, which does not short circuit.
            def binary| 5 (LHS RHS)
              if LHS then
```

```
    1
  else if RHS then
    1
  else
    0;

# Binary logical and, which does not short circuit.
def binary& 6 (LHS RHS)
  if !LHS then
    0
  else
    !!RHS;

# Define = with slightly lower precedence than relationals.
def binary = 9 (LHS RHS)
  !(LHS < RHS | LHS > RHS);

# Define ':' for sequencing: as a low-precedence operator that ignores operands
# and just returns the RHS.
def binary : 1 (x y) y;
```

Given the previous if/then/else support, we can also define interesting functions for I/O. For example, the following prints out a character whose "density" reflects the value passed in: the lower the value, the denser the character:

```
ready> extern putchard(char);
            ...
            ready> def printdensity(d)
              if d > 8 then
                putchard(32)  # ' '
              else if d > 4 then
                putchard(46)  # '.'
              else if d > 2 then
                putchard(43)  # '+'
              else
                putchard(42); # '*'
            ...
            ready> printdensity(1): printdensity(2): printdensity(3):
                   printdensity(4): printdensity(5): printdensity(9):
                   putchard(10);
            **++.
            Evaluated to 0.000000
```

Based on these simple primitive operations, we can start to define more interesting things. For example, here's a little function that determines the number of iterations it takes for a certain function in the complex plane to diverge:

```
# Determine whether the specific location diverges.
            # Solve for z = z^2 + c in the complex plane.
            def mandelconverger(real imag iters creal cimag)
              if iters > 255 | (real*real + imag*imag > 4) then
                iters
```

```
  else
    mandelconverger(real*real - imag*imag + creal,
                    2*real*imag + cimag,
                    iters+1, creal, cimag);

# Return the number of iterations required for the iteration to escape
def mandelconverge(real imag)
  mandelconverger(real, imag, 0, real, imag);
```

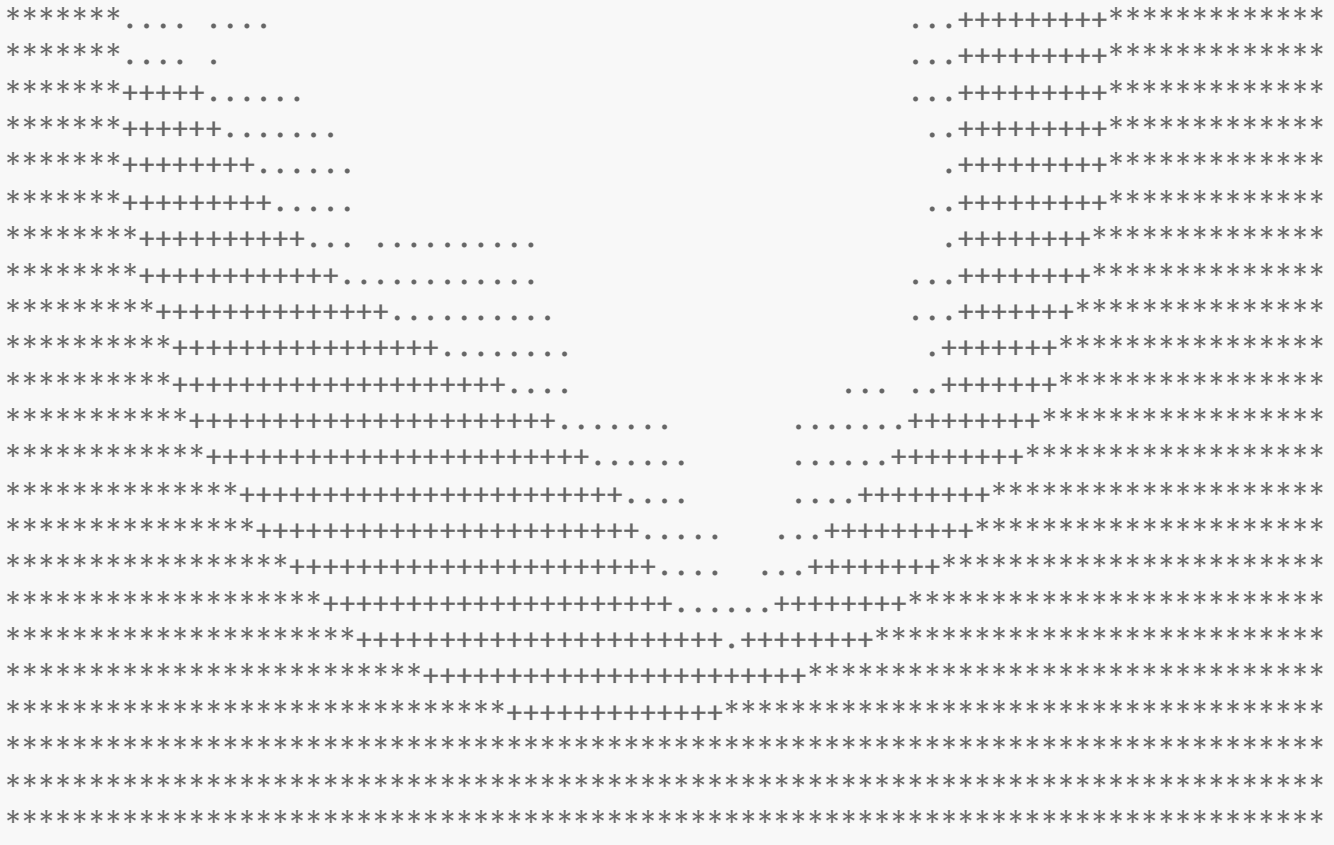
This "`z = z2 + c`" function is a beautiful little creature that is the basis for computation of the Mandelbrot Set. Our `mandelconverge` function returns the number of iterations that it takes for a complex orbit to escape, saturating to 255. This is not a very useful function by itself, but if you plot its value over a two-dimensional plane, you can see the Mandelbrot set. Given that we are limited to using putchard here, our amazing graphical output is limited, but we can whip together something using the density plotter above:

```
# Compute and plot the mandelbrot set with the specified 2 dimensional range
# info.
def mandelhelp(xmin xmax xstep   ymin ymax ystep)
  for y = ymin, y < ymax, ystep in (
    (for x = xmin, x < xmax, xstep in
       printdensity(mandelconverge(x,y)))
    : putchard(10)
  )

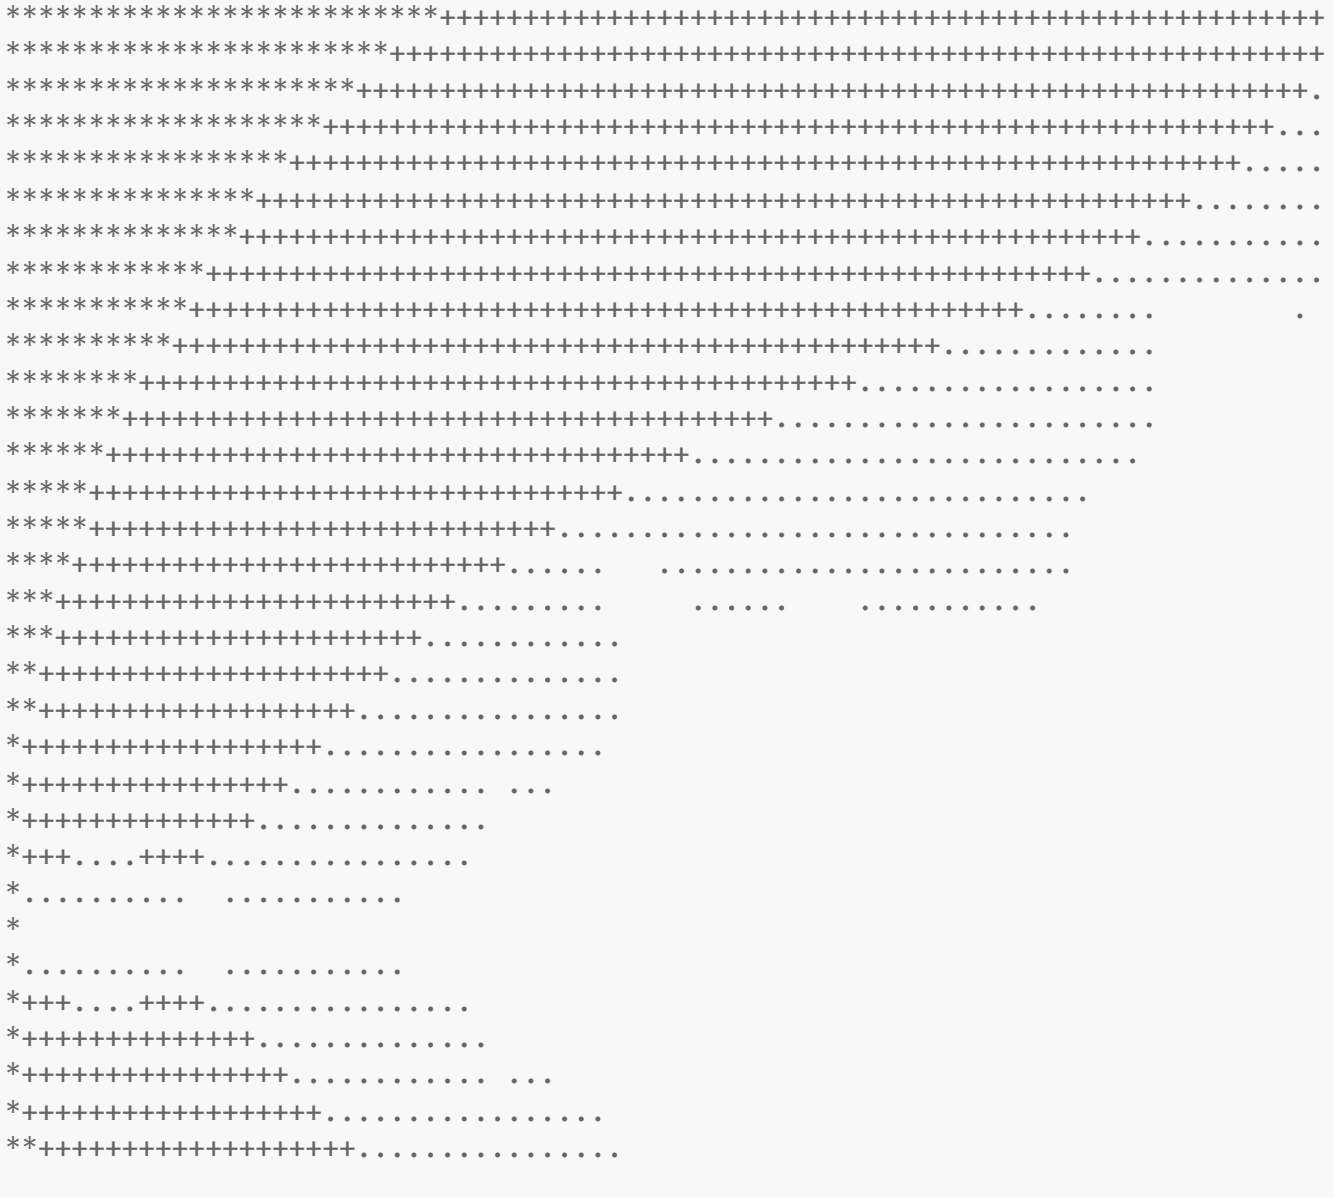
# mandel - This is a convenient helper function for plotting the mandelbrot set
# from the specified position with the specified Magnification.
def mandel(realstart imagstart realmag imagmag)
  mandelhelp(realstart, realstart+realmag*78, realmag,
             imagstart, imagstart+imagmag*40, imagmag);
```

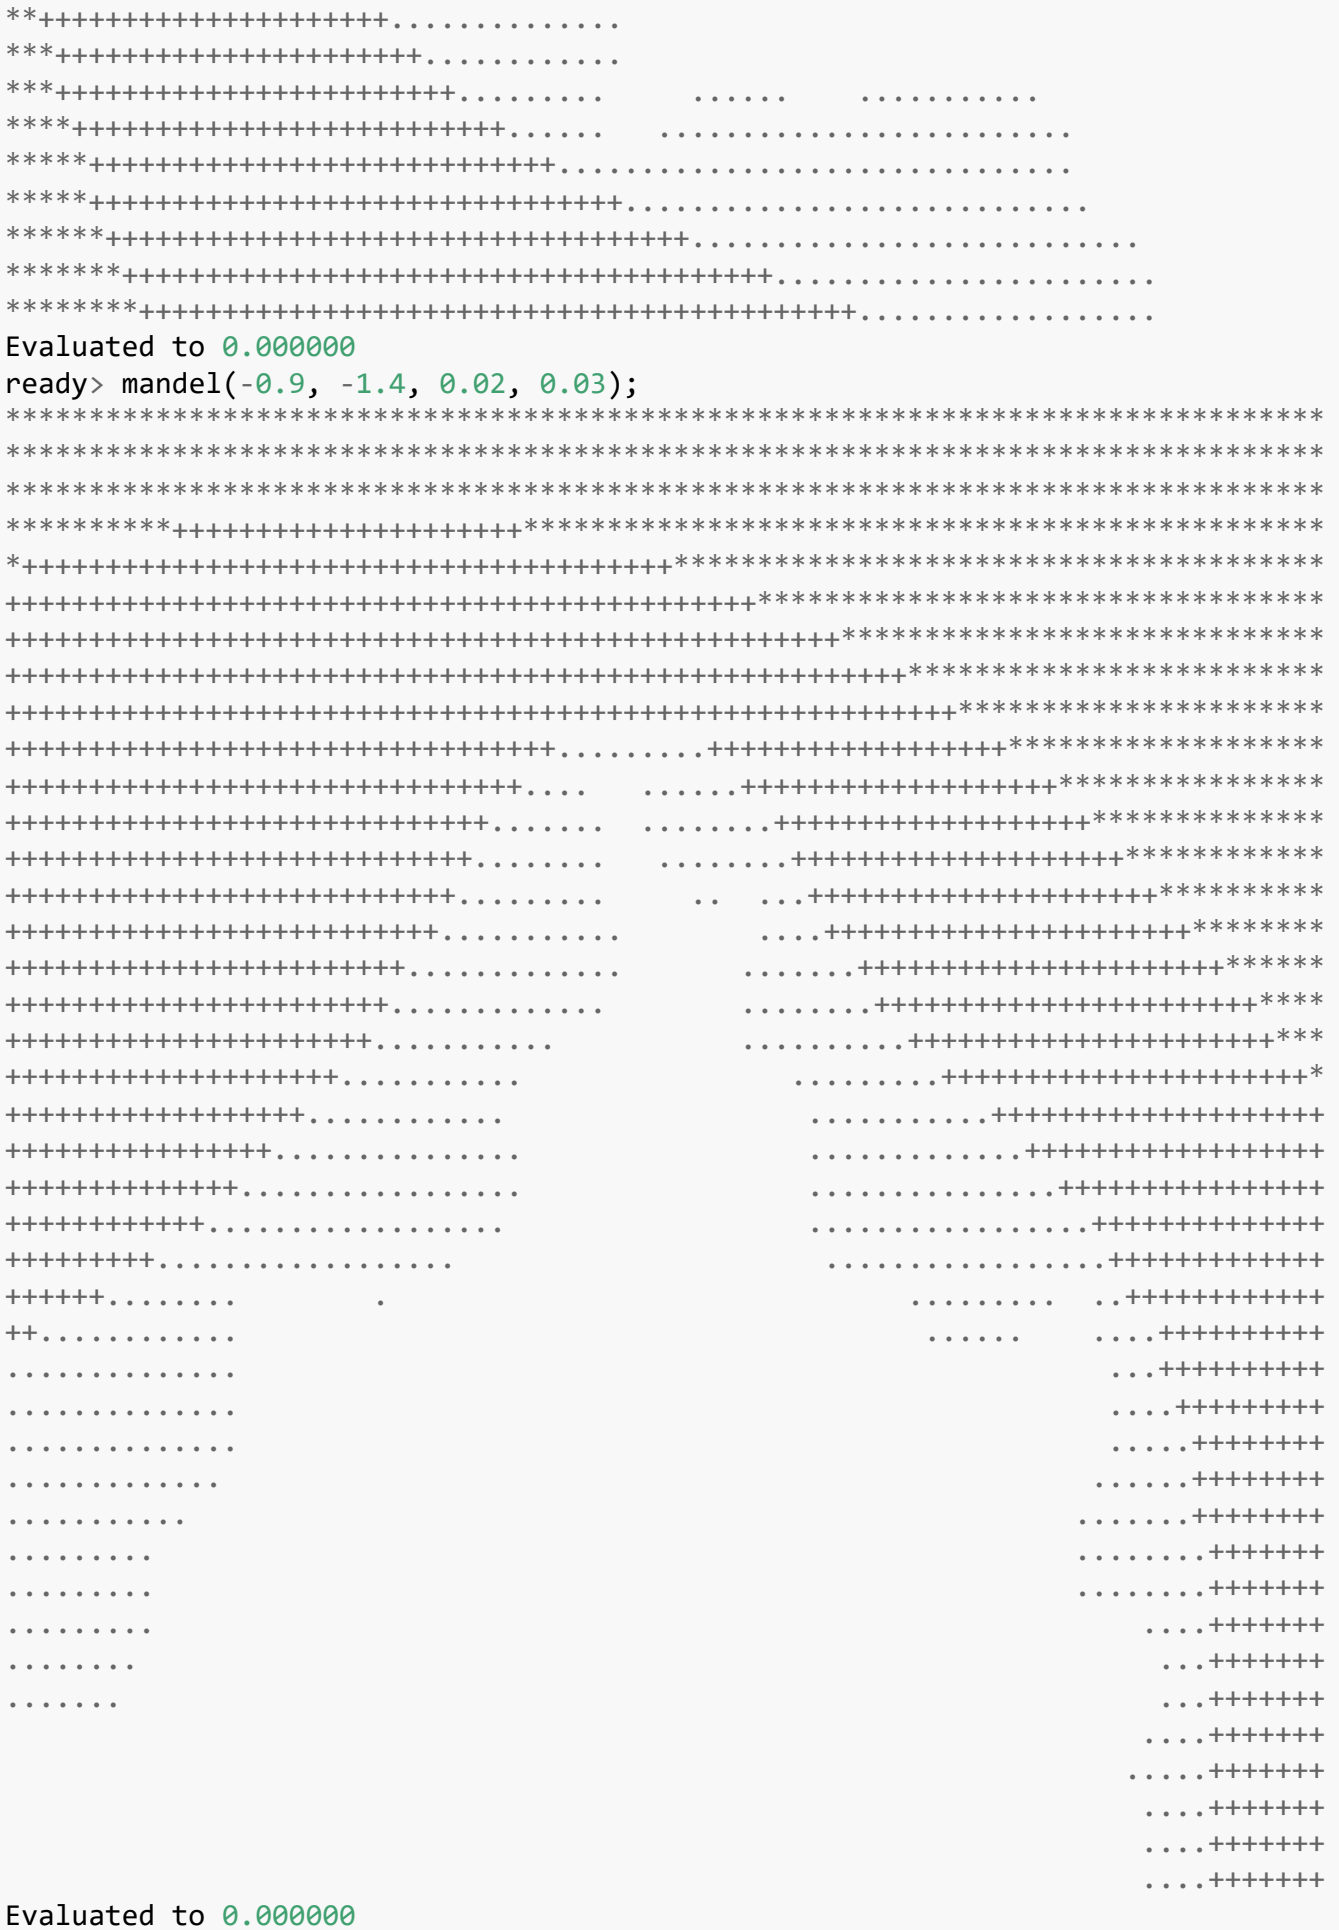
Given this, we can try plotting out the mandelbrot set! Lets try it out:

```
ready> mandel(-2.3, -1.3, 0.05, 0.07);
                              ++++++++++++
                          ++++++++++++++++++++
                      ++++++++++++++++++++++++++++
                  ++++++++++++++++++++++++++++++++++
                ++++++++++++++++++++..  ...++++++++
               +++++++++++++++++++++....  ...+++++++++
              ++++++++++++++++++++++.....   ...+++++++++
              ++++++++++++++++++++++....     ....+++++++++
             ++++++++++++++++++++++......      .....++++++++
             ++++++++++++++++++++.......       .......+++++++
             ++++++++++++++++++....                ... .+++++++
             ++++++++++++++++.......                  .+++++++
             +++++++++++++++..........                ...+++++++
             ++++++++++++............                 ...++++++++
             ++++++++++... ..........                   .++++++++
             +++++++++.....                             .++++++++
             +++++++......                              ..++++++++
             ++++++.......                              ..++++++++
             +++++......                                ..++++++++
```



```
Evaluated to 0.000000
ready> mandel(-2, -1, 0.02, 0.04);
```





```
Evaluated to 0.000000
ready> mandel(-0.9, -1.4, 0.02, 0.03);
Evaluated to 0.000000
ready> ^D
```

At this point, you may be starting to realize that Kaleidoscope is a real and powerful language. It may not be self-similar :), but it can be used to plot things that are!

With this, we conclude the "adding user-defined operators" chapter of the tutorial. We have successfully augmented our language, adding the ability to extend the language in the library, and we have shown how this can be used to build a simple but interesting end-user application in Kaleidoscope. At this point, Kaleidoscope can build a variety of applications that are functional and can call functions with side-effects, but it can't actually define and mutate a variable itself.

Strikingly, variable mutation is an important feature of some languages, and it is not at all obvious how to add support for mutable variables without having to add an "SSA construction" phase to your front-end. In the next chapter, we will describe how you can add variable mutation without building SSA in your front-end.

6.6. Full Code Listing ¶

Here is the complete code listing for our running example, enhanced with the support for user-defined operators. To build this example, use:

```
# Compile
            clang++ -g toy.cpp `llvm-config --cxxflags --ldflags --system-libs --libs core orc
            # Run
            ./toy
```

On some platforms, you will need to specify -rdynamic or -Wl,-export-dynamic when linking. This ensures that symbols defined in the main executable are exported to the dynamic linker and so are available for symbol resolution at run time. This is not needed if you compile your support code into a shared library, although doing that will cause problems on Windows.

Here is the code:

```
#include "../include/KaleidoscopeJIT.h"
            #include "llvm/ADT/APFloat.h"
            #include "llvm/ADT/STLExtras.h"
            #include "llvm/IR/BasicBlock.h"
            #include "llvm/IR/Constants.h"
            #include "llvm/IR/DerivedTypes.h"
            #include "llvm/IR/Function.h"
            #include "llvm/IR/IRBuilder.h"
            #include "llvm/IR/Instructions.h"
            #include "llvm/IR/LLVMContext.h"
            #include "llvm/IR/Module.h"
            #include "llvm/IR/PassManager.h"
            #include "llvm/IR/Type.h"
            #include "llvm/IR/Verifier.h"
            #include "llvm/Passes/PassBuilder.h"
            #include "llvm/Passes/StandardInstrumentations.h"
            #include "llvm/Support/TargetSelect.h"
            #include "llvm/Target/TargetMachine.h"
            #include "llvm/Transforms/InstCombine/InstCombine.h"
            #include "llvm/Transforms/Scalar.h"
```

```
#include "llvm/Transforms/Scalar/GVN.h"
#include "llvm/Transforms/Scalar/Reassociate.h"
#include "llvm/Transforms/Scalar/SimplifyCFG.h"
#include <algorithm>
#include <cassert>
#include <cctype>
#include <cstdint>
#include <cstdio>
#include <cstdlib>
#include <map>
#include <memory>
#include <string>
#include <vector>

Next: Extending the language: mutable variables / SSA construction

7. Kaleidoscope: Extending the Language: Mutable Variables ¶

7.1. Chapter 7 Introduction ¶

Welcome to Chapter 7 of the "Implementing a language with LLVM" tutorial. In chapters 1 through 6, we've built a very respectable, albeit simple, functional programming language. In our journey, we learned some parsing techniques, how to build and represent an AST, how to build LLVM IR, and how to optimize the resultant code as well as JIT compile it.

While Kaleidoscope is interesting as a functional language, the fact that it is functional makes it "too easy" to generate LLVM IR for it. In particular, a functional language makes it very easy to build LLVM IR directly in SSA form. Since LLVM requires that the input code be in SSA form, this is a very

nice property and it is often unclear to newcomers how to generate code for an imperative language with mutable variables.

The short (and happy) summary of this chapter is that there is no need for your front-end to build SSA form: LLVM provides highly tuned and well tested support for this, though the way it works is a bit unexpected for some.

7.2. Why is this a hard problem? ¶

To understand why mutable variables cause complexities in SSA construction, consider this extremely simple C example:

```
int G, H;
int test(_Bool Condition) {
  int X;
  if (Condition)
    X = G;
  else
    X = H;
  return X;
}
```

In this case, we have the variable "X", whose value depends on the path executed in the program. Because there are two different possible values for X before the return instruction, a PHI node is inserted to merge the two values. The LLVM IR that we want for this example looks like this:

```
@G = weak global i32 0   ; type of @G is i32*
@H = weak global i32 0   ; type of @H is i32*

define i32 @test(i1 %Condition) {
entry:
  br i1 %Condition, label %cond_true, label %cond_false

cond_true:
  %X.0 = load i32, i32* @G
  br label %cond_next

cond_false:
  %X.1 = load i32, i32* @H
  br label %cond_next

cond_next:
  %X.2 = phi i32 [ %X.1, %cond_false ], [ %X.0, %cond_true ]
  ret i32 %X.2
}
```

In this example, the loads from the G and H global variables are explicit in the LLVM IR, and they live in the then/else branches of the if statement (cond_true/cond_false). In order to merge the incoming values, the X.2 phi node in the cond_next block selects the right value to use based on where control flow is coming from: if control flow comes from the cond_false block, X.2 gets the

value of X.1. Alternatively, if control flow comes from cond_true, it gets the value of X.0. The intent of this chapter is not to explain the details of SSA form. For more information, see one of the many online references.

The question for this article is "who places the phi nodes when lowering assignments to mutable variables?". The issue here is that LLVM *requires* that its IR be in SSA form: there is no "non-ssa" mode for it. However, SSA construction requires non-trivial algorithms and data structures, so it is inconvenient and wasteful for every front-end to have to reproduce this logic.

7.3. Memory in LLVM ¶

The 'trick' here is that while LLVM does require all register values to be in SSA form, it does not require (or permit) memory objects to be in SSA form. In the example above, note that the loads from G and H are direct accesses to G and H: they are not renamed or versioned. This differs from some other compiler systems, which do try to version memory objects. In LLVM, instead of encoding dataflow analysis of memory into the LLVM IR, it is handled with Analysis Passes which are computed on demand.

With this in mind, the high-level idea is that we want to make a stack variable (which lives in memory, because it is on the stack) for each mutable object in a function. To take advantage of this trick, we need to talk about how LLVM represents stack variables.

In LLVM, all memory accesses are explicit with load/store instructions, and it is carefully designed not to have (or need) an "address-of" operator. Notice how the type of the @G/@H global variables is actually "i32*" even though the variable is defined as "i32". What this means is that @G defines *space* for an i32 in the global data area, but its *name* actually refers to the address for that space. Stack variables work the same way, except that instead of being declared with global variable definitions, they are declared with the LLVM alloca instruction:

```
define i32 @example() {
            entry:
              %X = alloca i32           ; type of %X is i32*.
              ...
              %tmp = load i32, i32* %X  ; load the stack value %X from the stack.
              %tmp2 = add i32 %tmp, 1   ; increment it
              store i32 %tmp2, i32* %X  ; store it back
              ...
```

This code shows an example of how you can declare and manipulate a stack variable in the LLVM IR. Stack memory allocated with the alloca instruction is fully general: you can pass the address of the stack slot to functions, you can store it in other variables, etc. In our example above, we could rewrite the example to use the alloca technique to avoid using a PHI node:

```
@G = weak global i32 0   ; type of @G is i32*
            @H = weak global i32 0   ; type of @H is i32*

            define i32 @test(i1 %Condition) {
            entry:
```

```
  %X = alloca i32           ; type of %X is i32*.
  br i1 %Condition, label %cond_true, label %cond_false

cond_true:
  %X.0 = load i32, i32* @G
  store i32 %X.0, i32* %X   ; Update X
  br label %cond_next

cond_false:
  %X.1 = load i32, i32* @H
  store i32 %X.1, i32* %X   ; Update X
  br label %cond_next

cond_next:
  %X.2 = load i32, i32* %X  ; Read X
  ret i32 %X.2
}
```

With this, we have discovered a way to handle arbitrary mutable variables without the need to create Phi nodes at all:

1. Each mutable variable becomes a stack allocation.
2. Each read of the variable becomes a load from the stack.
3. Each update of the variable becomes a store to the stack.
4. Taking the address of a variable just uses the stack address directly.

While this solution has solved our immediate problem, it introduced another one: we have now apparently introduced a lot of stack traffic for very simple and common operations, a major performance problem. Fortunately for us, the LLVM optimizer has a highly-tuned optimization pass named “mem2reg” that handles this case, promoting allocas like this into SSA registers, inserting Phi nodes as appropriate. If you run this example through the pass, for example, you’ll get:

```
$ llvm-as < example.ll | opt -passes=mem2reg | llvm-dis
@G = weak global i32 0
@H = weak global i32 0

define i32 @test(i1 %Condition) {
entry:
  br i1 %Condition, label %cond_true, label %cond_false

cond_true:
  %X.0 = load i32, i32* @G
  br label %cond_next

cond_false:
  %X.1 = load i32, i32* @H
  br label %cond_next

cond_next:
  %X.01 = phi i32 [ %X.1, %cond_false ], [ %X.0, %cond_true ]
  ret i32 %X.01
```

```
        }
```

The mem2reg pass implements the standard "iterated dominance frontier" algorithm for constructing SSA form and has a number of optimizations that speed up (very common) degenerate cases. The mem2reg optimization pass is the answer to dealing with mutable variables, and we highly recommend that you depend on it. Note that mem2reg only works on variables in certain circumstances:

1. mem2reg is alloca-driven: it looks for allocas and if it can handle them, it promotes them. It does not apply to global variables or heap allocations.
2. mem2reg only looks for alloca instructions in the entry block of the function. Being in the entry block guarantees that the alloca is only executed once, which makes analysis simpler.
3. mem2reg only promotes allocas whose uses are direct loads and stores. If the address of the stack object is passed to a function, or if any funny pointer arithmetic is involved, the alloca will not be promoted.
4. mem2reg only works on allocas of first class values (such as pointers, scalars and vectors), and only if the array size of the allocation is 1 (or missing in the .ll file). mem2reg is not capable of promoting structs or arrays to registers. Note that the "sroa" pass is more powerful and can promote structs, "unions", and arrays in many cases.

All of these properties are easy to satisfy for most imperative languages, and we'll illustrate it below with Kaleidoscope. The final question you may be asking is: should I bother with this nonsense for my front-end? Wouldn't it be better if I just did SSA construction directly, avoiding use of the mem2reg optimization pass? In short, we strongly recommend that you use this technique for building SSA form, unless there is an extremely good reason not to. Using this technique is:

- Proven and well tested: clang uses this technique for local mutable variables. As such, the most common clients of LLVM are using this to handle a bulk of their variables. You can be sure that bugs are found fast and fixed early.
- Extremely Fast: mem2reg has a number of special cases that make it fast in common cases as well as fully general. For example, it has fast-paths for variables that are only used in a single block, variables that only have one assignment point, good heuristics to avoid insertion of unneeded phi nodes, etc.
- Needed for debug info generation: Debug information in LLVM relies on having the address of the variable exposed so that debug info can be attached to it. This technique dovetails very naturally with this style of debug info.

If nothing else, this makes it much easier to get your front-end up and running, and is very simple to implement. Let's extend Kaleidoscope with mutable variables now!

7.4. Mutable Variables in Kaleidoscope ¶

Now that we know the sort of problem we want to tackle, let's see what this looks like in the context of our little Kaleidoscope language. We're going to add two features:

1. The ability to mutate variables with the '=' operator.
2. The ability to define new variables.

While the first item is really what this is about, we only have variables for incoming arguments as well as for induction variables, and redefining those only goes so far :). Also, the ability to define new variables is a useful thing regardless of whether you will be mutating them. Here's a motivating example that shows how we could use these:

```
# Define ':' for sequencing: as a low-precedence operator that ignores operands
            # and just returns the RHS.
            def binary : 1 (x y) y;

            # Recursive fib, we could do this before.
            def fib(x)
              if (x < 3) then
                1
              else
                fib(x-1)+fib(x-2);

            # Iterative fib.
            def fibi(x)
              var a = 1, b = 1, c in
              (for i = 3, i < x in
                 c = a + b :
                 a = b :
                 b = c) :
              b;

            # Call it.
            fibi(10);
```

In order to mutate variables, we have to change our existing variables to use the "alloca trick". Once we have that, we'll add our new operator, then extend Kaleidoscope to support new variable definitions.

7.5. Adjusting Existing Variables for Mutation ¶

The symbol table in Kaleidoscope is managed at code generation time by the '`NamedValues`' map. This map currently keeps track of the LLVM "Value*" that holds the double value for the named variable. In order to support mutation, we need to change this slightly, so that `NamedValues` holds the *memory location* of the variable in question. Note that this change is a refactoring: it changes the structure of the code, but does not (by itself) change the behavior of the compiler. All of these changes are isolated in the Kaleidoscope code generator.

At this point in Kaleidoscope's development, it only supports variables for two things: incoming arguments to functions and the induction variable of 'for' loops. For consistency, we'll allow

mutation of these variables in addition to other user-defined variables. This means that these will both need memory locations.

To start our transformation of Kaleidoscope, we'll change the `NamedValues` map so that it maps to AllocaInst* instead of Value*. Once we do this, the C++ compiler will tell us what parts of the code we need to update:

```
static std::map<std::string, AllocaInst*> NamedValues;
```

Also, since we will need to create these allocas, we'll use a helper function that ensures that the allocas are created in the entry block of the function:

```
/// CreateEntryBlockAlloca - Create an alloca instruction in the entry block of
            /// the function.  This is used for mutable variables etc.
            static AllocaInst *CreateEntryBlockAlloca(Function *TheFunction,
                                                      const std::string &VarName) {
              IRBuilder<> TmpB(&TheFunction->getEntryBlock(),
                               TheFunction->getEntryBlock().begin());
              return TmpB.CreateAlloca(Type::getDoubleTy(*TheContext), nullptr,
                                       VarName);
            }
```

This funny looking code creates an IRBuilder object that is pointing at the first instruction (.begin()) of the entry block. It then creates an alloca with the expected name and returns it. Because all values in Kaleidoscope are doubles, there is no need to pass in a type to use.

With this in place, the first functionality change we want to make belongs to variable references. In our new scheme, variables live on the stack, so code generating a reference to them actually needs to produce a load from the stack slot:

```
Value *VariableExprAST::codegen() {
              // Look this variable up in the function.
              AllocaInst *A = NamedValues[Name];
              if (!A)
                return LogErrorV("Unknown variable name");

              // Load the value.
              return Builder->CreateLoad(A->getAllocatedType(), A, Name.c_str());
            }
```

As you can see, this is pretty straightforward. Now we need to update the things that define the variables to set up the alloca. We'll start with `ForExprAST::codegen()` (see the full code listing for the unabridged code):

```
Function *TheFunction = Builder->GetInsertBlock()->getParent();

            // Create an alloca for the variable in the entry block.
            AllocaInst *Alloca = CreateEntryBlockAlloca(TheFunction, VarName);
```

```
  // Emit the start code first, without 'variable' in scope.
  Value *StartVal = Start->codegen();
  if (!StartVal)
    return nullptr;

  // Store the value into the alloca.
  Builder->CreateStore(StartVal, Alloca);
  ...

  // Compute the end condition.
  Value *EndCond = End->codegen();
  if (!EndCond)
    return nullptr;

  // Reload, increment, and restore the alloca.  This handles the case where
  // the body of the loop mutates the variable.
  Value *CurVar = Builder->CreateLoad(Alloca->getAllocatedType(), Alloca,
                                      VarName.c_str());
  Value *NextVar = Builder->CreateFAdd(CurVar, StepVal, "nextvar");
  Builder->CreateStore(NextVar, Alloca);
  ...
```

This code is virtually identical to the code before we allowed mutable variables. The big difference is that we no longer have to construct a PHI node, and we use load/store to access the variable as needed.

To support mutable argument variables, we need to also make allocas for them. The code for this is also pretty simple:

```
Function *FunctionAST::codegen() {
  ...
  Builder->SetInsertPoint(BB);

  // Record the function arguments in the NamedValues map.
  NamedValues.clear();
  for (auto &Arg : TheFunction->args()) {
    // Create an alloca for this variable.
    AllocaInst *Alloca = CreateEntryBlockAlloca(TheFunction, Arg.getName());

    // Store the initial value into the alloca.
    Builder->CreateStore(&Arg, Alloca);

    // Add arguments to variable symbol table.
    NamedValues[std::string(Arg.getName())] = Alloca;
  }

  if (Value *RetVal = Body->codegen()) {
    ...
```

For each argument, we make an alloca, store the input value to the function into the alloca, and register the alloca as the memory location for the argument. This method gets invoked by

`FunctionAST::codegen()` right after it sets up the entry block for the function.

The final missing piece is adding the mem2reg pass, which allows us to get good codegen once again:

```
// Promote allocas to registers.
            TheFPM->add(createPromoteMemoryToRegisterPass());
            // Do simple "peephole" optimizations and bit-twiddling optzns.
            TheFPM->add(createInstructionCombiningPass());
            // Reassociate expressions.
            TheFPM->add(createReassociatePass());
            ...
```

It is interesting to see what the code looks like before and after the mem2reg optimization runs. For example, this is the before/after code for our recursive fib function. Before the optimization:

```
define double @fib(double %x) {
            entry:
              %x1 = alloca double
              store double %x, double* %x1
              %x2 = load double, double* %x1
              %cmptmp = fcmp ult double %x2, 3.000000e+00
              %booltmp = uitofp i1 %cmptmp to double
              %ifcond = fcmp one double %booltmp, 0.000000e+00
              br i1 %ifcond, label %then, label %else

            then:       ; preds = %entry
              br label %ifcont

            else:       ; preds = %entry
              %x3 = load double, double* %x1
              %subtmp = fsub double %x3, 1.000000e+00
              %calltmp = call double @fib(double %subtmp)
              %x4 = load double, double* %x1
              %subtmp5 = fsub double %x4, 2.000000e+00
              %calltmp6 = call double @fib(double %subtmp5)
              %addtmp = fadd double %calltmp, %calltmp6
              br label %ifcont

            ifcont:     ; preds = %else, %then
              %iftmp = phi double [ 1.000000e+00, %then ], [ %addtmp, %else ]
              ret double %iftmp
            }
```

Here there is only one variable (x, the input argument) but you can still see the extremely simple-minded code generation strategy we are using. In the entry block, an alloca is created, and the initial input value is stored into it. Each reference to the variable does a reload from the stack. Also, note that we didn't modify the if/then/else expression, so it still inserts a PHI node. While we could make an alloca for it, it is actually easier to create a PHI node for it, so we still just make the PHI.

Here is the code after the mem2reg pass runs:

```
define double @fib(double %x) {
entry:
  %cmptmp = fcmp ult double %x, 3.000000e+00
  %booltmp = uitofp i1 %cmptmp to double
  %ifcond = fcmp one double %booltmp, 0.000000e+00
  br i1 %ifcond, label %then, label %else

then:
  br label %ifcont

else:
  %subtmp = fsub double %x, 1.000000e+00
  %calltmp = call double @fib(double %subtmp)
  %subtmp5 = fsub double %x, 2.000000e+00
  %calltmp6 = call double @fib(double %subtmp5)
  %addtmp = fadd double %calltmp, %calltmp6
  br label %ifcont

ifcont:     ; preds = %else, %then
  %iftmp = phi double [ 1.000000e+00, %then ], [ %addtmp, %else ]
  ret double %iftmp
}
```

This is a trivial case for mem2reg, since there are no redefinitions of the variable. The point of showing this is to calm your tension about inserting such blatant inefficiencies :).

After the rest of the optimizers run, we get:

```
define double @fib(double %x) {
entry:
  %cmptmp = fcmp ult double %x, 3.000000e+00
  %booltmp = uitofp i1 %cmptmp to double
  %ifcond = fcmp ueq double %booltmp, 0.000000e+00
  br i1 %ifcond, label %else, label %ifcont

else:
  %subtmp = fsub double %x, 1.000000e+00
  %calltmp = call double @fib(double %subtmp)
  %subtmp5 = fsub double %x, 2.000000e+00
  %calltmp6 = call double @fib(double %subtmp5)
  %addtmp = fadd double %calltmp, %calltmp6
  ret double %addtmp

ifcont:
  ret double 1.000000e+00
}
```

Here we see that the simplifycfg pass decided to clone the return instruction into the end of the ‘else’ block. This allowed it to eliminate some branches and the PHI node.

Now that all symbol table references are updated to use stack variables, we’ll add the assignment operator.

7.6. New Assignment Operator ¶

With our current framework, adding a new assignment operator is really simple. We will parse it just like any other binary operator, but handle it internally (instead of allowing the user to define it). The first step is to set a precedence:

```
int main() {
              // Install standard binary operators.
              // 1 is lowest precedence.
              BinopPrecedence['='] = 2;
              BinopPrecedence['<'] = 10;
              BinopPrecedence['+'] = 20;
              BinopPrecedence['-'] = 20;
```

Now that the parser knows the precedence of the binary operator, it takes care of all the parsing and AST generation. We just need to implement codegen for the assignment operator. This looks like:

```
Value *BinaryExprAST::codegen() {
              // Special case '=' because we don't want to emit the LHS as an expression.
              if (Op == '=') {
                // This assume we're building without RTTI because LLVM builds that way by
                // default. If you build LLVM with RTTI this can be changed to a
                // dynamic_cast for automatic error checking.
                VariableExprAST *LHSE = static_cast<VariableExprAST*>(LHS.get());
                if (!LHSE)
                  return LogErrorV("destination of '=' must be a variable");
```

Unlike the rest of the binary operators, our assignment operator doesn't follow the "emit LHS, emit RHS, do computation" model. As such, it is handled as a special case before the other binary operators are handled. The other strange thing is that it requires the LHS to be a variable. It is invalid to have "(x+1) = expr" - only things like "x = expr" are allowed.

```
  // Codegen the RHS.
              Value *Val = RHS->codegen();
              if (!Val)
                return nullptr;

              // Look up the name.
              Value *Variable = NamedValues[LHSE->getName()];
              if (!Variable)
                return LogErrorV("Unknown variable name");

              Builder->CreateStore(Val, Variable);
              return Val;
            }
            ...
```

Once we have the variable, codegen'ing the assignment is straightforward: we emit the RHS of the assignment, create a store, and return the computed value. Returning a value allows for chained assignments like "X = (Y = Z)".

Now that we have an assignment operator, we can mutate loop variables and arguments. For example, we can now run code like this:

```
# Function to print a double.
            extern printd(x);

            # Define ':' for sequencing: as a low-precedence operator that ignores operands
            # and just returns the RHS.
            def binary : 1 (x y) y;

            def test(x)
              printd(x) :
              x = 4 :
              printd(x);

            test(123);
```

When run, this example prints "123" and then "4", showing that we did actually mutate the value! Okay, we have now officially implemented our goal: getting this to work requires SSA construction in the general case. However, to be really useful, we want the ability to define our own local variables, let's add this next!

7.7. User-defined Local Variables ¶

Adding var/in is just like any other extension we made to Kaleidoscope: we extend the lexer, the parser, the AST and the code generator. The first step for adding our new 'var/in' construct is to extend the lexer. As before, this is pretty trivial, the code looks like this:

```
enum Token {
              ...
              // var definition
              tok_var = -13
            ...
            }
            ...
            static int gettok() {
            ...
                if (IdentifierStr == "in")
                  return tok_in;
                if (IdentifierStr == "binary")
                  return tok_binary;
                if (IdentifierStr == "unary")
                  return tok_unary;
                if (IdentifierStr == "var")
                  return tok_var;
                return tok_identifier;
            ...
```

The next step is to define the AST node that we will construct. For var/in, it looks like this:

```
/// VarExprAST - Expression class for var/in
            class VarExprAST : public ExprAST {
              std::vector<std::pair<std::string, std::unique_ptr<ExprAST>>> VarNames;
              std::unique_ptr<ExprAST> Body;

            public:
              VarExprAST(std::vector<std::pair<std::string, std::unique_ptr<ExprAST>>> VarNames
                         std::unique_ptr<ExprAST> Body)
                : VarNames(std::move(VarNames)), Body(std::move(Body)) {}

              Value *codegen() override;
            };
```

var/in allows a list of names to be defined all at once, and each name can optionally have an initializer value. As such, we capture this information in the VarNames vector. Also, var/in has a body, this body is allowed to access the variables defined by the var/in.

With this in place, we can define the parser pieces. The first thing we do is add it as a primary expression:

```
/// primary
            ///   ::= identifierexpr
            ///   ::= numberexpr
            ///   ::= parenexpr
            ///   ::= ifexpr
            ///   ::= forexpr
            ///   ::= varexpr
            static std::unique_ptr<ExprAST> ParsePrimary() {
              switch (CurTok) {
              default:
                return LogError("unknown token when expecting an expression");
              case tok_identifier:
                return ParseIdentifierExpr();
              case tok_number:
                return ParseNumberExpr();
              case '(':
                return ParseParenExpr();
              case tok_if:
                return ParseIfExpr();
              case tok_for:
                return ParseForExpr();
              case tok_var:
                return ParseVarExpr();
              }
            }
```

Next we define ParseVarExpr:

```
/// varexpr ::= 'var' identifier ('=' expression)?
            //                    (',' identifier ('=' expression)?)* 'in' expression
```

```
            static std::unique_ptr<ExprAST> ParseVarExpr() {
              getNextToken();  // eat the var.

              std::vector<std::pair<std::string, std::unique_ptr<ExprAST>>> VarNames;

              // At least one variable name is required.
              if (CurTok != tok_identifier)
                return LogError("expected identifier after var");
```

The first part of this code parses the list of identifier/expr pairs into the local `VarNames` vector.

```
while (true) {
              std::string Name = IdentifierStr;
              getNextToken();  // eat identifier.

              // Read the optional initializer.
              std::unique_ptr<ExprAST> Init;
              if (CurTok == '=') {
                getNextToken(); // eat the '='.

                Init = ParseExpression();
                if (!Init) return nullptr;
              }

              VarNames.push_back(std::make_pair(Name, std::move(Init)));

              // End of var list, exit loop.
              if (CurTok != ',') break;
              getNextToken(); // eat the ','.

              if (CurTok != tok_identifier)
                return LogError("expected identifier list after var");
            }
```

Once all the variables are parsed, we then parse the body and create the AST node:

```
  // At this point, we have to have 'in'.
              if (CurTok != tok_in)
                return LogError("expected 'in' keyword after 'var'");
              getNextToken();  // eat 'in'.

              auto Body = ParseExpression();
              if (!Body)
                return nullptr;

              return std::make_unique<VarExprAST>(std::move(VarNames),
                                                  std::move(Body));
            }
```

Now that we can parse and represent the code, we need to support emission of LLVM IR for it. This code starts out with:

```
Value *VarExprAST::codegen() {
              std::vector<AllocaInst *> OldBindings;

              Function *TheFunction = Builder->GetInsertBlock()->getParent();

              // Register all variables and emit their initializer.
              for (unsigned i = 0, e = VarNames.size(); i != e; ++i) {
                const std::string &VarName = VarNames[i].first;
                ExprAST *Init = VarNames[i].second.get();
```

Basically it loops over all the variables, installing them one at a time. For each variable we put into the symbol table, we remember the previous value that we replace in OldBindings.

```
  // Emit the initializer before adding the variable to scope, this prevents
              // the initializer from referencing the variable itself, and permits stuff
              // like this:
              //  var a = 1 in
              //    var a = a in ...   # refers to outer 'a'.
              Value *InitVal;
              if (Init) {
                InitVal = Init->codegen();
                if (!InitVal)
                  return nullptr;
              } else { // If not specified, use 0.0.
                InitVal = ConstantFP::get(*TheContext, APFloat(0.0));
              }

              AllocaInst *Alloca = CreateEntryBlockAlloca(TheFunction, VarName);
              Builder->CreateStore(InitVal, Alloca);

              // Remember the old variable binding so that we can restore the binding when
              // we unrecurse.
              OldBindings.push_back(NamedValues[VarName]);

              // Remember this binding.
              NamedValues[VarName] = Alloca;
            }
```

There are more comments here than code. The basic idea is that we emit the initializer, create the alloca, then update the symbol table to point to it. Once all the variables are installed in the symbol table, we evaluate the body of the var/in expression:

```
// Codegen the body, now that all vars are in scope.
            Value *BodyVal = Body->codegen();
            if (!BodyVal)
              return nullptr;
```

Finally, before returning, we restore the previous variable bindings:

```
  // Pop all our variables from scope.
            for (unsigned i = 0, e = VarNames.size(); i != e; ++i)
              NamedValues[VarNames[i].first] = OldBindings[i];

            // Return the body computation.
            return BodyVal;
          }
```

The end result of all of this is that we get properly scoped variable definitions, and we even (trivially) allow mutation of them :).

With this, we completed what we set out to do. Our nice iterative fib example from the intro compiles and runs just fine. The mem2reg pass optimizes all of our stack variables into SSA registers, inserting PHI nodes where needed, and our front-end remains simple: no “iterated dominance frontier” computation anywhere in sight.

7.8. Full Code Listing ¶

Here is the complete code listing for our running example, enhanced with mutable variables and var/in support. To build this example, use:

```
# Compile
            clang++ -g toy.cpp `llvm-config --cxxflags --ldflags --system-libs --libs core orc
            # Run
            ./toy
```

Here is the code:

```
#include "../include/KaleidoscopeJIT.h"
            #include "llvm/ADT/APFloat.h"
            #include "llvm/ADT/STLExtras.h"
            #include "llvm/IR/BasicBlock.h"
            #include "llvm/IR/Constants.h"
            #include "llvm/IR/DerivedTypes.h"
            #include "llvm/IR/Function.h"
            #include "llvm/IR/IRBuilder.h"
            #include "llvm/IR/Instructions.h"
            #include "llvm/IR/LLVMContext.h"
            #include "llvm/IR/Module.h"
            #include "llvm/IR/PassManager.h"
            #include "llvm/IR/Type.h"
            #include "llvm/IR/Verifier.h"
            #include "llvm/Passes/PassBuilder.h"
            #include "llvm/Passes/StandardInstrumentations.h"
            #include "llvm/Support/TargetSelect.h"
            #include "llvm/Target/TargetMachine.h"
            #include "llvm/Transforms/InstCombine/InstCombine.h"
            #include "llvm/Transforms/Scalar.h"
            #include "llvm/Transforms/Scalar/GVN.h"
            #include "llvm/Transforms/Scalar/Reassociate.h"
            #include "llvm/Transforms/Scalar/SimplifyCFG.h"
```

```

Next: Compiling to Object Code

8. Kaleidoscope: Compiling to Object Code ¶

8.1. Chapter 8 Introduction ¶

Welcome to Chapter 8 of the "Implementing a language with LLVM" tutorial. This chapter describes how to compile our language down to object files.

8.2. Choosing a target ¶

LLVM has native support for cross-compilation. You can compile to the architecture of your current machine, or just as easily compile for other architectures. In this tutorial, we'll target the current machine.

To specify the architecture that you want to target, we use a string called a "target triple". This takes the form `<arch><sub>-<vendor>-<sys>-<abi>` (see the cross compilation docs).

As an example, we can see what clang thinks is our current target triple:

```
$ clang --version | grep Target
            Target: x86_64-unknown-linux-gnu
```

Running this command may show something different on your machine as you might be using a different architecture or operating system to me.

Fortunately, we don't need to hard-code a target triple to target the current machine. LLVM provides `sys::getDefaultTargetTriple`, which returns the target triple of the current machine.

```
auto TargetTriple = sys::getDefaultTargetTriple();
```

LLVM doesn't require us to link in all the target functionality. For example, if we're just using the JIT, we don't need the assembly printers. Similarly, if we're only targeting certain architectures, we can only link in the functionality for those architectures.

For this example, we'll initialize all the targets for emitting object code.

```
InitializeAllTargetInfos();
            InitializeAllTargets();
            InitializeAllTargetMCs();
            InitializeAllAsmParsers();
            InitializeAllAsmPrinters();
```

We can now use our target triple to get a `Target`:

```
std::string Error;
            auto Target = TargetRegistry::lookupTarget(TargetTriple, Error);

            // Print an error and exit if we couldn't find the requested target.
            // This generally occurs if we've forgotten to initialise the
            // TargetRegistry or we have a bogus target triple.
            if (!Target) {
              errs() << Error;
              return 1;
            }
```

8.3. Target Machine ¶

We will also need a `TargetMachine`. This class provides a complete machine description of the machine we're targeting. If we want to target a specific feature (such as SSE) or a specific CPU (such as Intel's Sandylake), we do so now.

To see which features and CPUs that LLVM knows about, we can use `llc`. For example, let's look at x86:

```
$ llvm-as < /dev/null | llc -march=x86 -mattr=help
            Available CPUs for this target:
```

```
    amdfam10      - Select the amdfam10 processor.
    athlon        - Select the athlon processor.
    athlon-4      - Select the athlon-4 processor.
    ...

  Available features for this target:

    16bit-mode            - 16-bit mode (i8086).
    32bit-mode            - 32-bit mode (80386).
    3dnow                 - Enable 3DNow! instructions.
    3dnowa                - Enable 3DNow! Athlon instructions.
    ...
```

For our example, we'll use the generic CPU without any additional feature or target option.

```
auto CPU = "generic";
            auto Features = "";

            TargetOptions opt;
            auto TargetMachine = Target->createTargetMachine(TargetTriple, CPU, Features, opt,
```

8.4. Configuring the Module ¶

We're now ready to configure our module, to specify the target and data layout. This isn't strictly necessary, but the frontend performance guide recommends this. Optimizations benefit from knowing about the target and data layout.

```
TheModule->setDataLayout(TargetMachine->createDataLayout());
            TheModule->setTargetTriple(TargetTriple);
```

8.5. Emit Object Code ¶

We're ready to emit object code! Let's define where we want to write our file to:

```
auto Filename = "output.o";
            std::error_code EC;
            raw_fd_ostream dest(Filename, EC, sys::fs::OF_None);

            if (EC) {
              errs() << "Could not open file: " << EC.message();
              return 1;
            }
```

Finally, we define a pass that emits object code, then we run that pass:

```
legacy::PassManager pass;
            auto FileType = CodeGenFileType::ObjectFile;

            if (TargetMachine->addPassesToEmitFile(pass, dest, nullptr, FileType)) {
```

```
            errs() << "TargetMachine can't emit a file of this type";
            return 1;
        }

        pass.run(*TheModule);
        dest.flush();
```

8.6. Putting It All Together ¶

Does it work? Let's give it a try. We need to compile our code, but note that the arguments to `llvm-config` are different to the previous chapters.

```
$ clang++ -g -O3 toy.cpp `llvm-config --cxxflags --ldflags --system-libs --libs all` -o toy
```

Let's run it, and define a simple `average` function. Press Ctrl-D when you're done.

```
$ ./toy
        ready> def average(x y) (x + y) * 0.5;
        ^D
        Wrote output.o
```

We have an object file! To test it, let's write a simple program and link it with our output. Here's the source code:

```
#include <iostream>

        extern "C" {
            double average(double, double);
        }

        int main() {
            std::cout << "average of 3.0 and 4.0: " << average(3.0, 4.0) << std::endl;
        }
```

We link our program to output.o and check the result is what we expected:

```
$ clang++ main.cpp output.o -o main
        $ ./main
        average of 3.0 and 4.0: 3.5
```

8.7. Full Code Listing ¶

```
#include "llvm/ADT/APFloat.h"
        #include "llvm/ADT/STLExtras.h"
        #include "llvm/IR/BasicBlock.h"
        #include "llvm/IR/Constants.h"
        #include "llvm/IR/DerivedTypes.h"

Next: Adding Debug Information

9. Kaleidoscope: Adding Debug Information ¶

9.1. Chapter 9 Introduction ¶

Welcome to Chapter 9 of the "Implementing a language with LLVM" tutorial. In chapters 1 through 8, we've built a decent little programming language with functions and variables. What happens if something goes wrong though, how do you debug your program?

Source level debugging uses formatted data that helps a debugger translate from binary and the state of the machine back to the source that the programmer wrote. In LLVM we generally use a format called DWARF. DWARF is a compact encoding that represents types, source locations, and variable locations.

The short summary of this chapter is that we'll go through the various things you have to add to a programming language to support debug info, and how you translate that into DWARF.

Caveat: For now we can't debug via the JIT, so we'll need to compile our program down to something small and standalone. As part of this we'll make a few modifications to the running of

the language and how programs are compiled. This means that we'll have a source file with a simple program written in Kaleidoscope rather than the interactive JIT. It does involve a limitation that we can only have one "top level" command at a time to reduce the number of changes necessary.

Here's the sample program we'll be compiling:

```
def fib(x)
  if x < 3 then
    1
  else
    fib(x-1)+fib(x-2);

fib(10)
```

9.2. Why is this a hard problem? ¶

Debug information is a hard problem for a few different reasons - mostly centered around optimized code. First, optimization makes keeping source locations more difficult. In LLVM IR we keep the original source location for each IR level instruction on the instruction. Optimization passes should keep the source locations for newly created instructions, but merged instructions only get to keep a single location - this can cause jumping around when stepping through optimized programs. Secondly, optimization can move variables in ways that are either optimized out, shared in memory with other variables, or difficult to track. For the purposes of this tutorial we're going to avoid optimization (as you'll see with one of the next sets of patches).

9.3. Ahead-of-Time Compilation Mode ¶

To highlight only the aspects of adding debug information to a source language without needing to worry about the complexities of JIT debugging we're going to make a few changes to Kaleidoscope to support compiling the IR emitted by the front end into a simple standalone program that you can execute, debug, and see results.

First we make our anonymous function that contains our top level statement be our "main":

```
-    auto Proto = std::make_unique<PrototypeAST>("", std::vector<std::string>());
+    auto Proto = std::make_unique<PrototypeAST>("main", std::vector<std::string>());
```

just with the simple change of giving it a name.

Then we're going to remove the command line code wherever it exists:

```
@@ -1129,7 +1129,6 @@ static void HandleTopLevelExpression() {
 /// top ::= definition | external | expression | ';'
 static void MainLoop() {

   BinopPrecedence['*'] = 40; // highest.

   // Prime the first token.
-  fprintf(stderr, "ready> ");
   getNextToken();
```

Lastly we're going to disable all of the optimization passes and the JIT so that the only thing that happens after we're done parsing and generating code is that the LLVM IR goes to standard error:

```
@@ -1108,17 +1108,8 @@ static void HandleExtern() {

   OurFPM.add(createCFGSimplificationPass());
-
+#endif
   OurFPM.doInitialization();

   // Set the global so the code gen can use this.
```

This relatively small set of changes get us to the point that we can compile our piece of Kaleidoscope language down to an executable program via this command line:

```
Kaleidoscope-Ch9 < fib.ks | & clang -x ir -
```

which gives an a.out/a.exe in the current working directory.

9.4. Compile Unit ¶

The top level container for a section of code in DWARF is a compile unit. This contains the type and function data for an individual translation unit (read: one file of source code). So the first thing we need to do is construct one for our fib.ks file.

9.5. DWARF Emission Setup ¶

Similar to the `IRBuilder` class we have a DIBuilder class that helps in constructing debug metadata for an LLVM IR file. It corresponds 1:1 similarly to `IRBuilder` and LLVM IR, but with nicer names. Using it does require that you be more familiar with DWARF terminology than you needed to be with `IRBuilder` and `Instruction` names, but if you read through the general documentation on the Metadata Format it should be a little more clear. We'll be using this class to construct all of our IR level descriptions. Construction for it takes a module so we need to construct it shortly after we construct our module. We've left it as a global static variable to make it a bit easier to use.

Next we're going to create a small container to cache some of our frequent data. The first will be our compile unit, but we'll also write a bit of code for our one type since we won't have to worry about multiple typed expressions:

```
static std::unique_ptr<DIBuilder> DBuilder;

struct DebugInfo {
  DICompileUnit *TheCU;
  DIType *DblTy;

  DIType *getDoubleTy();
} KSDbgInfo;

DIType *DebugInfo::getDoubleTy() {
  if (DblTy)
    return DblTy;

  DblTy = DBuilder->createBasicType("double", 64, dwarf::DW_ATE_float);
  return DblTy;
}
```

And then later on in `main` when we're constructing our module:

```
DBuilder = std::make_unique<DIBuilder>(*TheModule);

KSDbgInfo.TheCU = DBuilder->createCompileUnit(
    dwarf::DW_LANG_C, DBuilder->createFile("fib.ks", "."),
    "Kaleidoscope Compiler", false, "", 0);
```

There are a couple of things to note here. First, while we're producing a compile unit for a language called Kaleidoscope we used the language constant for C. This is because a debugger wouldn't necessarily understand the calling conventions or default ABI for a language it doesn't recognize and we follow the C ABI in our LLVM code generation so it's the closest thing to accurate.

This ensures we can actually call functions from the debugger and have them execute. Secondly, you'll see the "fib.ks" in the call to `createCompileUnit`. This is a default hard coded value since we're using shell redirection to put our source into the Kaleidoscope compiler. In a usual front end you'd have an input file name and it would go there.

One last thing as part of emitting debug information via DIBuilder is that we need to "finalize" the debug information. The reasons are part of the underlying API for DIBuilder, but make sure you do this near the end of main:

```
DBuilder->finalize();
```

before you dump out the module.

9.6. Functions ¶

Now that we have our `Compile Unit` and our source locations, we can add function definitions to the debug info. So in `FunctionAST::codegen()` we add a few lines of code to describe a context for our subprogram, in this case the "File", and the actual definition of the function itself.

So the context:

```
DIFile *Unit = DBuilder->createFile(KSDbgInfo.TheCU->getFilename(),
                                    KSDbgInfo.TheCU->getDirectory());
```

giving us an DIFile and asking the `Compile Unit` we created above for the directory and filename where we are currently. Then, for now, we use some source locations of 0 (since our AST doesn't currently have source location information) and construct our function definition:

```
DIScope *FContext = Unit;
unsigned LineNo = 0;
unsigned ScopeLine = 0;
DISubprogram *SP = DBuilder->createFunction(
    FContext, P.getName(), StringRef(), Unit, LineNo,
    CreateFunctionType(TheFunction->arg_size()),
    ScopeLine,
    DINode::FlagPrototyped,
    DISubprogram::SPFlagDefinition);
TheFunction->setSubprogram(SP);
```

and we now have an DISubprogram that contains a reference to all of our metadata for the function.

9.7. Source Locations ¶

The most important thing for debug information is accurate source location - this makes it possible to map your source code back. We have a problem though, Kaleidoscope really doesn't have any source location information in the lexer or parser so we'll need to add it.

```
struct SourceLocation {
  int Line;
  int Col;
};
static SourceLocation CurLoc;
static SourceLocation LexLoc = {1, 0};

static int advance() {
  int LastChar = getchar();

  if (LastChar == '\n' || LastChar == '\r') {
    LexLoc.Line++;
    LexLoc.Col = 0;
  } else
    LexLoc.Col++;
  return LastChar;
}
```

In this set of code we've added some functionality on how to keep track of the line and column of the "source file". As we lex every token we set our current current "lexical location" to the assorted line and column for the beginning of the token. We do this by overriding all of the previous calls to `getchar()` with our new `advance()` that keeps track of the information and then we have added to all of our AST classes a source location:

```
class ExprAST {
  SourceLocation Loc;

  public:
    ExprAST(SourceLocation Loc = CurLoc) : Loc(Loc) {}
    virtual ~ExprAST() {}
    virtual Value* codegen() = 0;
    int getLine() const { return Loc.Line; }
    int getCol() const { return Loc.Col; }
    virtual raw_ostream &dump(raw_ostream &out, int ind) {
      return out << ':' << getLine() << ':' << getCol() << '\n';
    }
```

that we pass down through when we create a new expression:

```
LHS = std::make_unique<BinaryExprAST>(BinLoc, BinOp, std::move(LHS),
                                      std::move(RHS));
```

giving us locations for each of our expressions and variables.

To make sure that every instruction gets proper source location information, we have to tell `Builder` whenever we're at a new source location. We use a small helper function for this:

```
void DebugInfo::emitLocation(ExprAST *AST) {
  if (!AST)
    return Builder->SetCurrentDebugLocation(DebugLoc());
  DIScope *Scope;
  if (LexicalBlocks.empty())
    Scope = TheCU;
```

```
  else
    Scope = LexicalBlocks.back();
  Builder->SetCurrentDebugLocation(
      DILocation::get(Scope->getContext(), AST->getLine(), AST->getCol(), Scope));
}
```

This both tells the main `IRBuilder` where we are, but also what scope we're in. The scope can either be on compile-unit level or be the nearest enclosing lexical block like the current function. To represent this we create a stack of scopes in `DebugInfo`:

```
std::vector<DIScope *> LexicalBlocks;
```

and push the scope (function) to the top of the stack when we start generating the code for each function:

```
KSDbgInfo.LexicalBlocks.push_back(SP);
```

Also, we may not forget to pop the scope back off of the scope stack at the end of the code generation for the function:

```
// Pop off the lexical block for the function since we added it
// unconditionally.
KSDbgInfo.LexicalBlocks.pop_back();
```

Then we make sure to emit the location every time we start to generate code for a new AST object:

```
KSDbgInfo.emitLocation(this);
```

9.8. Variables ¶

Now that we have functions, we need to be able to print out the variables we have in scope. Let's get our function arguments set up so we can get decent backtraces and see how our functions are being called. It isn't a lot of code, and we generally handle it when we're creating the argument allocas in `FunctionAST::codegen`.

```
// Record the function arguments in the NamedValues map.
NamedValues.clear();
unsigned ArgIdx = 0;
for (auto &Arg : TheFunction->args()) {
  // Create an alloca for this variable.
  AllocaInst *Alloca = CreateEntryBlockAlloca(TheFunction, Arg.getName());

  // Create a debug descriptor for the variable.
  DILocalVariable *D = DBuilder->createParameterVariable(
      SP, Arg.getName(), ++ArgIdx, Unit, LineNo, KSDbgInfo.getDoubleTy(),
      true);

  DBuilder->insertDeclare(Alloca, D, DBuilder->createExpression(),
                          DILocation::get(SP->getContext(), LineNo, 0, SP),
                          Builder->GetInsertBlock());
```

```
  // Store the initial value into the alloca.
  Builder->CreateStore(&Arg, Alloca);

  // Add arguments to variable symbol table.
  NamedValues[std::string(Arg.getName())] = Alloca;
}
```

Here we're first creating the variable, giving it the scope (SP), the name, source location, type, and since it's an argument, the argument index. Next, we create a `#dbg_declare` record to indicate at the IR level that we've got a variable in an alloca (and it gives a starting location for the variable), and setting a source location for the beginning of the scope on the declare.

One interesting thing to note at this point is that various debuggers have assumptions based on how code and debug information was generated for them in the past. In this case we need to do a little bit of a hack to avoid generating line information for the function prologue so that the debugger knows to skip over those instructions when setting a breakpoint. So in `FunctionAST::CodeGen` we add some more lines:

```
// Unset the location for the prologue emission (leading instructions with no
// location in a function are considered part of the prologue and the debugger
// will run past them when breaking on a function)
KSDbgInfo.emitLocation(nullptr);
```

and then emit a new location when we actually start generating code for the body of the function:

```
KSDbgInfo.emitLocation(Body.get());
```

With this we have enough debug information to set breakpoints in functions, print out argument variables, and call functions. Not too bad for just a few simple lines of code!

9.9. Full Code Listing ¶

Here is the complete code listing for our running example, enhanced with debug information. To build this example, use:

```
# Compile
clang++ -g toy.cpp `llvm-config --cxxflags --ldflags --system-libs --libs core orcjit native` -
# Run
./toy
```

Here is the code:

```

Next: Conclusion and other useful LLVM tidbits

10. Kaleidoscope: Conclusion and other useful LLVM tidbits ¶

10.1. Tutorial Conclusion ¶

Welcome to the final chapter of the “Implementing a language with LLVM” tutorial. In the course of this tutorial, we have grown our little Kaleidoscope language from being a useless toy, to being a semi-interesting (but probably still useless) toy. :)

It is interesting to see how far we've come, and how little code it has taken. We built the entire lexer, parser, AST, code generator, an interactive run-loop (with a JIT!), and emitted debug information in standalone executables - all in under 1000 lines of (non-comment/non-blank) code.

Our little language supports a couple of interesting features: it supports user defined binary and unary operators, it uses JIT compilation for immediate evaluation, and it supports a few control flow constructs with SSA construction.

Part of the idea of this tutorial was to show you how easy and fun it can be to define, build, and play with languages. Building a compiler need not be a scary or mystical process! Now that you've seen some of the basics, I strongly encourage you to take the code and hack on it. For example, try adding:

- **global variables** - While global variables have questionable value in modern software engineering, they are often useful when putting together quick little hacks like the Kaleidoscope compiler itself. Fortunately, our current setup makes it very easy to add global variables: just have value lookup check to see if an unresolved variable is in the global variable symbol table before rejecting it. To create a new global variable, make an instance of the LLVM `GlobalVariable` class.
- **typed variables** - Kaleidoscope currently only supports variables of type double. This gives the language a very nice elegance, because only supporting one type means that you never have to specify types. Different languages have different ways of handling this. The easiest way is to require the user to specify types for every variable definition, and record the type of the variable in the symbol table along with its Value*.
- **arrays, structs, vectors, etc** - Once you add types, you can start extending the type system in all sorts of interesting ways. Simple arrays are very easy and are quite useful for many different applications. Adding them is mostly an exercise in learning how the LLVM getelementptr instruction works: it is so nifty/unconventional, it has its own FAQ!
- **standard runtime** - Our current language allows the user to access arbitrary external functions, and we use it for things like "printd" and "putchard". As you extend the language to add higher-level constructs, often these constructs make the most sense if they are lowered to calls into a language-supplied runtime. For example, if you add hash tables to the language, it would probably make sense to add the routines to a runtime, instead of inlining them all the way.
- **memory management** - Currently we can only access the stack in Kaleidoscope. It would also be useful to be able to allocate heap memory, either with calls to the standard libc malloc/free interface or with a garbage collector. If you would like to use garbage collection, note that LLVM fully supports Accurate Garbage Collection including algorithms that move objects and need to scan/update the stack.
- **exception handling support** - LLVM supports generation of zero cost exceptions which interoperate with code compiled in other languages. You could also generate code by implicitly

making every function return an error value and checking it. You could also make explicit use of setjmp/longjmp. There are many different ways to go here.

- **object orientation, generics, database access, complex numbers, geometric programming, ...** - Really, there is no end of crazy features that you can add to the language.
- **unusual domains** - We've been talking about applying LLVM to a domain that many people are interested in: building a compiler for a specific language. However, there are many other domains that can use compiler technology that are not typically considered. For example, LLVM has been used to implement OpenGL graphics acceleration, translate C++ code to ActionScript, and many other cute and clever things. Maybe you will be the first to JIT compile a regular expression interpreter into native code with LLVM?

Have fun - try doing something crazy and unusual. Building a language like everyone else always has, is much less fun than trying something a little crazy or off the wall and seeing how it turns out. If you get stuck or want to talk about it, please post on the LLVM forums: it has lots of people who are interested in languages and are often willing to help out.

Before we end this tutorial, I want to talk about some "tips and tricks" for generating LLVM IR. These are some of the more subtle things that may not be obvious, but are very useful if you want to take advantage of LLVM's capabilities.

10.2. Properties of the LLVM IR ¶

We have a couple of common questions about code in the LLVM IR form - let's just get these out of the way right now, shall we?

10.2.1. Target Independence ¶

Kaleidoscope is an example of a "portable language": any program written in Kaleidoscope will work the same way on any target that it runs on. Many other languages have this property, e.g. lisp, java, haskell, javascript, python, etc (note that while these languages are portable, not all their libraries are).

One nice aspect of LLVM is that it is often capable of preserving target independence in the IR: you can take the LLVM IR for a Kaleidoscope-compiled program and run it on any target that LLVM supports, even emitting C code and compiling that on targets that LLVM doesn't support natively. You can trivially tell that the Kaleidoscope compiler generates target-independent code because it never queries for any target-specific information when generating code.

The fact that LLVM provides a compact, target-independent, representation for code gets a lot of people excited. Unfortunately, these people are usually thinking about C or a language from the C family when they are asking questions about language portability. I say "unfortunately", because there is really no way to make (fully general) C code portable, other than shipping the source code around (and of course, C source code is not actually portable in general either - ever port a really old application from 32- to 64-bits?).

The problem with C (again, in its full generality) is that it is heavily laden with target specific assumptions. As one simple example, the preprocessor often destructively removes target-independence from the code when it processes the input text:

```
#ifdef __i386__
              int X = 1;
            #else
              int X = 42;
            #endif
```

While it is possible to engineer more and more complex solutions to problems like this, it cannot be solved in full generality in a way that is better than shipping the actual source code.

That said, there are interesting subsets of C that can be made portable. If you are willing to fix primitive types to a fixed size (say int = 32-bits, and long = 64-bits), don't care about ABI compatibility with existing binaries, and are willing to give up some other minor features, you can have portable code. This can make sense for specialized domains such as an in-kernel language.

10.2.2. Safety Guarantees ¶

Many of the languages above are also "safe" languages: it is impossible for a program written in Java to corrupt its address space and crash the process (assuming the JVM has no bugs). Safety is an interesting property that requires a combination of language design, runtime support, and often operating system support.

It is certainly possible to implement a safe language in LLVM, but LLVM IR does not itself guarantee safety. The LLVM IR allows unsafe pointer casts, use after free bugs, buffer over-runs, and a variety of other problems. Safety needs to be implemented as a layer on top of LLVM and, conveniently, several groups have investigated this. Ask on the LLVM forums if you are interested in more details.

10.2.3. Language-Specific Optimizations ¶

One thing about LLVM that turns off many people is that it does not solve all the world's problems in one system. One specific complaint is that people perceive LLVM as being incapable of performing high-level language-specific optimization: LLVM "loses too much information". Here are a few observations about this:

First, you're right that LLVM does lose information. For example, as of this writing, there is no way to distinguish in the LLVM IR whether an SSA-value came from a C "int" or a C "long" on an ILP32 machine (other than debug info). Both get compiled down to an 'i32' value and the information about what it came from is lost. The more general issue here, is that the LLVM type system uses "structural equivalence" instead of "name equivalence". Another place this surprises people is if you have two types in a high-level language that have the same structure (e.g. two different structs that have a single int field): these types will compile down into a single LLVM type and it will be impossible to tell what it came from.

Second, while LLVM does lose information, LLVM is not a fixed target: we continue to enhance and improve it in many different ways. In addition to adding new features (LLVM did not always support exceptions or debug info), we also extend the IR to capture important information for optimization (e.g. whether an argument is sign or zero extended, information about pointers aliasing, etc). Many of the enhancements are user-driven: people want LLVM to include some specific feature, so they go ahead and extend it.

Third, it is *possible and easy* to add language-specific optimizations, and you have a number of choices in how to do it. As one trivial example, it is easy to add language-specific optimization passes that "know" things about code compiled for a language. In the case of the C family, there is an optimization pass that "knows" about the standard C library functions. If you call "exit(0)" in main(), it knows that it is safe to optimize that into "return 0;" because C specifies what the 'exit' function does.

In addition to simple library knowledge, it is possible to embed a variety of other language-specific information into the LLVM IR. If you have a specific need and run into a wall, please bring the topic up on the llvm-dev list. At the very worst, you can always treat LLVM as if it were a "dumb code generator" and implement the high-level optimizations you desire in your front-end, on the language-specific AST.

10.3. Tips and Tricks ¶

There is a variety of useful tips and tricks that you come to know after working on/with LLVM that aren't obvious at first glance. Instead of letting everyone rediscover them, this section talks about some of these issues.

10.3.1. Implementing portable offsetof/sizeof ¶

One interesting thing that comes up, if you are trying to keep the code generated by your compiler "target independent", is that you often need to know the size of some LLVM type or the offset of some field in an llvm structure. For example, you might need to pass the size of a type into a function that allocates memory.

Unfortunately, this can vary widely across targets: for example the width of a pointer is trivially target-specific. However, there is a clever way to use the getelementptr instruction that allows you to compute this in a portable way.

10.3.2. Garbage Collected Stack Frames ¶

Some languages want to explicitly manage their stack frames, often so that they are garbage collected or to allow easy implementation of closures. There are often better ways to implement these features than explicit stack frames, but LLVM does support them, if you want. It requires your front-end to convert the code into Continuation Passing Style and the use of tail calls (which LLVM also supports).
